The role that VUR plays in UTI development and the controversies surrounding it will be discussed in greater detail later in this chapter and in Chapter 137. VUR has been identified in 1% to 2% of all newborns, but it is found in 25% to 40% of children after their first episode of UTI (Hellerstein, 1995; Greenfield and Wan, 1996). **Although VUR may be present in a child who has suffered a pyelonephritic infection, it is important to remember that the majority of children who have suffered from pyelonephritis do not have VUR.** Rushton and Majd found that in children suffering DMSA-proven pyelonephritis, only 37% were shown to have VUR (Rushton et al, 1992). Kidneys associated with higher-grade VUR (grades III-IV), however, were twice as likely to exhibit pyelonephritic changes on DMSA scan (Rushton et al, 1992). The role that VUR plays in UTI development is complex and not completely understood. Variables such as reflux grade, patient age, gender of the child, and presence of bowel and bladder dysfunction most likely contribute to UTI development in the presence of VUR.

Sexual Activity

Previous studies have shown that sexual activity increases the risk of UTI development. Kunin (1968) demonstrated that sexually active females suffer more UTIs than sexually inactive females. This finding has prompted some to suggest that UTI may be used as a marker of teenage sexual activity (Nguyen and Weir, 2002). However, this relationship remains unclear.

Bladder and Bowel Dysfunction

Bladder and bowel dysfunction, also known as dysfunctional elimination syndrome, is known to contribute to pediatric UTI and VUR. Koff and coworkers (1998) originally coined the term *dysfunctional elimination syndrome*, which defined children who were without any neurologic disorder but who suffered from infrequent voiding, constipation, and/or bladder overactivity. Generally, in addressing children with bladder dysfunction, there are two different entities: (1) overactive bladder and (2) dysfunctional voiding.

Dysfunctional voiding terminology is used to describe children with no neurologic issues who exhibit increased activity of their pelvic floor during voiding (Sillen, 2008). Overactive bladder is defined as urinary urgency with or without urge incontinence, usually with frequency and nocturia (Wein and Rovner, 2002). Children suffering from dysfunctional elimination will commonly present for evaluation of such symptoms as recurrent UTIs (with or without fever), daytime or nighttime urinary incontinence, urinary urgency, urinary frequency, constipation, and/or encopresis.

Children suffering bladder dysfunction are relatively common. In a study of more than 3500 school-age children, Hellström and coworkers (1990) found that 6% of girls and 3.7% of boys had daytime urinary incontinence and more than 8% of the girls showed a history of UTI. Another population-based study examined 1127 children aged 6 to 9 years and found that 29% reported at least one symptom suggestive of bladder dysfunction. Of these children, 9.4% of the girls and 2.8% of the boys had a reported history of a previous UTI (Hansen et al, 1997).

There also seems to be a significant association between bladder and bowel dysfunction and VUR. Bladder overactivity alone has been identified in 8% to 75% of children who also were found to have VUR (Taylor et al, 1982; Koff and Murtagh, 1983; Griffiths and Scholtmeijer, 1987; van Gool et al, 1992; Scholtmeijer and Nijman, 1994; Koff et al, 1998; Yeung et al, 2006). When examining children with VUR, the prevalence of all bladder dysfunction is reported to be between 18% and 50% (Snodgrass, 1991, 1998; van Gool et al, 1992; Scholtmeijer and Nijman, 1994; Koff et al, 1998; Homayoon et al, 2005; Yeung et al, 2006). When Koff and coworkers introduced the concept of dysfunctional elimination syndrome in 1998 they reported it to be present in 46% of their cohort suffering from VUR.

Treatment of a child's bladder and bowel issues reduces recurrent UTIs and improves VUR resolution. Treating children suffering from bladder overactivity with anticholinergics alone resulted in VUR resolution or improvement in 44% to 79% of children (Koff and Murtagh, 1983; Homayoon et al, 1995; Scholtmeijer and Nijman, 1994). Treatment of children suffering from dysfunctional voiding with biofeedback resulted in VUR resolution in 55% to 63% of cases and improvement in VUR grade after 1 year of therapy (Palmer et al, 2002; Kibar et al, 2007). Treating bladder dysfunction improves a child's incontinence and reduces the risk of UTI development. Schulman and coworkers (1999) treated 366 patients referred for voiding dysfunction with various treatments including antibiotic prophylaxis, biofeedback, anticholinergics, and psychological counseling. After a mean of 22 months, treatment resulted in the resolution of daytime wetting in 45% of patients, improvement in daytime incontinence in 37% of patients, and improvement or cure of nighttime wetting in 69% of patients. Sixty-four percent of the children never developed another UTI, and VUR resolved in 53% of patients. Treatment of constipation improves daytime and nighttime urinary incontinence and helps reduce the incidence of recurrent UTIs. In a study by Loening-Baucke (1997), 234 patients were treated for constipation. At baseline, 46% of these patients suffered from either daytime and/or nighttime urinary incontinence, whereas 11% had suffered at least one UTI. The UTIs were more common in constipated girls compared to constipated boys. Follow-up at least 12 months after starting constipation therapies showed that constipation was successfully relieved in 52% of the children. Relief of constipation resulted in the disappearance of daytime urinary incontinence in 89% and enuresis in 63%, and disappearance of all UTIs in all patients who were without any genitourinary tract anatomic abnormalities.

Neurogenic Bladder

Children with neurogenic bladders and elevated bladder storage pressures risk hydronephrosis and renal damage from these increased pressures. In addition to this increased pressure, the physiologic effects of UTI have also been demonstrated to increase intrarenal pelvic pressures and to contribute to an even greater likelihood of renal damage in these individuals (Hansen et al, 2003). When

left untreated, children with neurogenic bladders that fill or empty at abnormally high pressures appear to be at higher risk of developing UTIs and renal damage, possibly because of their inability to clear the bacteria spontaneously. Clean intermittent catheterizations facilitate the emptying of the bladders of patients with neurogenic bladder and lower chronic bladder distention and bladder pressure. Multiple studies demonstrate that 40% to 80% of individuals who intermittently catheterize develop chronic bacteriuria and/or pyuria and most are asymptomatic. Importantly, this catheter-associated asymptomatic bacteriuria (ASB) appears to lack morbidity most of the time (Geraniotis et al, 1988; de la Hunt et al, 1989; Joseph et al, 1989; Gribble and Puterman, 1993; Johnson et al, 1994; Schlager et al, 1995). Ottolini and coworkers (1995) concluded that in the absence of VUR, ASB in patients managed with clean intermittent catheterization is not a significant risk factor for renal damage and does not require antibiotic therapy. In addition, despite the fact that most of these children have urine colonized with bacteria, most can undergo urodynamic studies without the need for prophylactic antibiotics (Shekarritz et al, 1999).

Some clinicians prescribe daily prophylactic antibiotics for children who perform chronic clean intermittent catheterization. This practice may delay or decrease bacteriuria in the short-term, but in the long term these prophylactic antibiotics have not been shown to be beneficial and instead may lead to the development of bacterial resistance (Johnson et al, 1994; Clarke et al, 2005). Studies have also been performed evaluating the use of different catheters and their effect on UTI development. The use of sterile versus nonsterile, single versus multiuse, and lubricated versus nonlubricated catheters have shown no benefit in reducing the risk of UTI development (Schlager et al, 1995; Moore et al, 2007). Bakke and Vollset (1993) identified that risk factors for UTI development in men and women treated with intermittent catheterization included high mean catheterization volume in women and low frequency of catheterization in men. In addition, they found that patients managed with prophylactic antibiotics were less prone to developing bacteriuria, but were more prone to developing clinical UTIs. These findings point toward the role that timely, scheduled catheterizations play in preventing UTIs in those patients managed with clean intermittent catheterization.

Iatrogenic Factors

Catheter-associated UTI is the most common nosocomial infection, accounting for more than one million cases each year in U.S. hospitals and nursing homes (Tambyah and Maki, 2000). The risk of UTI increases with the duration that the catheter is in place, and the overall incidence of bacteriuria is 8% and ranges from 3% to 10% per day (Sedor and Mulholland, 1999). In children, nosocomial UTIs account for 6% to 18% of nosocomial infections on pediatric hospital services (Ford-Jones et al, 1989; Lohr et al, 1989). Nosocomial UTIs typically necessitate one extra hospital day per patient or nearly one million extra hospital days annually in the United States (Foxman, 2002). A 2000 report estimated that each episode of nosocomial UTI added \$676 to each hospital bill, and the annual cost of nosocomial UTI in the United States that year was between \$424 and \$451 million (Saint, 2000). The best way to avoid this morbidity and its related cost is the judicious use of urinary catheters and the removal of urethral catheters in hospitalized patients as soon as they are no longer medically necessary.

Immune Status

Generally, UTIs in young, healthy women are benign conditions with no long-term effects. In contrast, UTIs in young children and geriatric adults seem to be more complicated, with increased morbidity and long-term consequences (Shortliffe and McCue, 2002). Although this contrasting paradigm is incompletely understood, we know that the immune system is diminished at either end of the age spectrum, which may make younger and older individuals more

susceptible to urinary infections. Clearly, the first few months of life appear to be the time of greatest risk for the development of UTI (Chang and Shortliffe, 2006). This increased susceptibility may in part be a result of an immature immune system. Serum IgG is lowest from age 1 to 3 months, and serum IgA is also found in lower concentrations during the first several months of life and is known to be absent or almost absent along the urothelium during this time (Svanborg Eden et al, 1985; Flidner et al, 1986; Yoder and Polin, 1986). Urinary secretory IgA and total IgA increase during the first year of life and are higher in children who are breastfed (James-Ellison et al, 1997). Currently, the exact benefits of breastfeeding in UTI prevention remain unclear, but some case-control studies do confer a protective effect in breastfed children (Hanson, 1998). Pisacane and coworkers (1992) showed that full or partial breastfeeding may provide a protective effect against UTIs in the first 6 months of life.

The incidence of UTI among both women and men who are seropositive for HIV is also greater compared to the general population (Evans et al, 1995; Schonwald et al, 1999). This same trend holds true for children infected with the HIV virus, with 20% suffering bacterial UTIs with both common and opportunistic infections (Grattan-Smith et al, 1992). However, children with primary immunodeficiency diseases do not generally appear to be more prone to developing UTIs (Montini et al, 2011). Children with primary antibody-deficiency states as well as those with severe combined immunodeficiency syndromes affecting both T-cell and B-cell function, who are known to be prone to multiple bacterial infections, actually suffer very few UTIs (Sideras, 1995). When UTIs do develop in these children, associated abnormalities of their genitourinary anatomy commonly play a role (Forbes et al, 1976; International Nijmegen Breakage Syndrome Study Group, 2000). **Therefore, children with these immunologic disorders should be evaluated in a similar fashion to nonimmunocompromised children.**

When discussing the role that defects in one's immune system may play in UTI development, one should also consider the role that a strengthened immune system can play in UTI prevention. Based on these thoughts, there have been attempts to develop UTI vaccines. Since the mid-1990s, several vaccine approaches have been explored, including the use of heat-killed whole bacteria, bacterial cell extracts, and purified UPEC-associated virulence factors as antigens (Barber et al, 2013). A vaccination using a vaginal suppository containing 10 heat-killed strains of uropathogenic bacteria, known as Solco-Urovac, was studied in women (Uehling et al, 2003; Hopkins et al, 2007). In phase 2 clinical trials it was shown to reduce the risk of *E. coli*-associated UTI development in sexually active women between the ages of 20 and 50 years with a history of recurrent UTI. Unfortunately, no phase 3 trial was ever initiated, namely because there were no statistically significant levels in anti-*E. coli* antibody levels between vaccinated and placebo-control groups.

Other bacterial factors have been targeted as possible vaccine candidates, including the type 1 pilus-associated adhesin FimH and UPEC-associated iron acquisition systems. Vaccination with a purified FimH coupled with its periplasmic chaperone FimC has offered protection against UPEC in both murine and primate cystitis models (Langermann et al, 1997, 2000; Thankavel et al, 1997). Pathogenic UTI-causing bacteria rely on iron chelating molecules and receptors that allow them to scavenge essential iron from the host (Wiles et al, 2008). The use of purified bacterial iron receptor proteins for vaccination has shown mixed results. Two iron receptors tested as vaccines in mice, IreA and LutA, provided protection against cystitis, whereas vaccination with another iron receptor, Hma, has demonstrated protection against pyelonephritis, but not cystitis (Alteri et al, 2009).

These preliminary studies highlight how the focus on different virulence factors may serve as valuable vaccination candidates to prevent UTI from developing. However, similar to our current experience with anticancer chemotherapeutics, we must remember that the use of such factors in vaccine target development may result in inadvertent effects on members of the endogenous microfloras that

naturally colonize our bodies (Barber et al, 2013). Certain delivery methods and other adjuvants may be used in the future to prevent such side effects, and certainly such therapeutics may be useful for individuals susceptible to UTI development, whereas in others the costs and risks may not warrant vaccination.

KEY POINTS: HOST RISK FACTORS

- There is a multitude of host factors that may make a child more susceptible to UTI development.
- The only time when UTIs are more prevalent in boys than in girls is at less than 1 year of age.
- Circumcision reduces the rate of UTI development in the first 6 months of life by almost tenfold.
- Dysfunctional elimination syndrome is an important factor contributing to pediatric UTI development, and treatment of a child's bladder and bowel issues reduces recurrent UTIs and improves VUR resolution.
- In the absence of VUR, ASB in patients managed with clean intermittent catheterization is not a significant risk factor for renal damage and does not require antibiotic therapy.
- Catheter-associated UTI is the most common nosocomial infection and the majority of these infections may be prevented with the judicious use of indwelling catheters.

CLASSIFICATION OF PEDIATRIC URINARY TRACT INFECTIONS

There are several ways to classify UTIs: as complicated versus uncomplicated, as upper (pyelonephritis) versus lower (cystitis), and as first infection versus recurrent infections. A complicated UTI describes infections in individuals who have anatomic or functional abnormalities or the presence of foreign bodies such as ureteral stents or indwelling urethral catheters. This classification, however, may not be best applied to children, as infections in neonates or infants are presumed to be complicated because of the common occurrence of urinary tract anatomic abnormalities and the high risk of morbidity in these young patients (Benador et al, 1997; Smellie et al, 1998).

UTIs are usually classified as involving the upper urinary tracts, based on the patient's clinical symptoms. Children are generally assumed to have pyelonephritis when they present with a UTI associated with high fevers, nausea, vomiting, flank pain, or lethargy. On the other hand, cystitis is suspected when the child is afebrile and has only lower urinary tract symptoms including urinary urgency, frequency or dysuria, malodorous urine, and/or suprapubic tenderness. However using a child's presenting clinical symptoms to classify UTIs into lower and upper urinary tract involvement is not 100% accurate. DMSA scans are considered the gold standard for diagnosing a pyelonephritic infection (Fig. 127-4). Studies using DMSA scans have shown that although the majority of patients with fever and systemic clinical findings consistent with acute pyelonephritis (APN) have positive renal scans, there is still a high false-positive rate when relying on symptoms alone to distinguish pyelonephritis from cystitis. Rushton and Majd (1992) and Tappin and coworkers (1989) demonstrated that in patients presenting with fever and systemic symptoms, only 50% to 66% demonstrated acute inflammatory changes on DMSA scans. In addition, a small subset of patients who present with afebrile, seemingly lower UTIs may have a positive DMSA scan consistent with APN (Verboven et al, 1990). Differentiation of cystitis and pyelonephritis can also be difficult in children based on the nonspecific symptoms that children may present with at the time of their infection. This is especially true in infants younger than 90 days who commonly present with symptoms that are difficult to interpret, such as failure to thrive, diarrhea, irritability, lethargy, malodorous urine, asymptomatic jaundice, oliguria, or polyuria (Garcia and Nager, 2002; Chang and Shortliffe, 2006).

Recurrent UTIs can be further subdivided into unresolved bacteriuria, bacterial persistence, and reinfection. Unresolved

Figure 127-4. Representative DMSA scan showing right medial upper pole cortical defect consistent with scarring as indicated by arrow.

bacteriuria is most commonly caused by inadequate bacterial therapy, which could be secondary to noncompliance, antibiotic malabsorption, suboptimal drug metabolism, and resistant uropathogens that were unresponsive to the attempted therapy (Pewitt and Schaffer, 1997). In these instances, repeated directed treatment based on bacterial sensitivities determined by proper urine culture will typically result in resolution of the infection.

Bacterial persistence and reinfection occur after sterile urine has been documented following previous UTI therapy. In cases of bacterial persistence, typically the nidus causing the infection has not been eradicated. Usually the same pathogen is documented on urine cultures during subsequent UTI episodes, despite negative cultures after previous antibiotic treatment. The uropathogen typically resides in a location that is shielded from antimicrobial therapy. Protected sites include anatomic abnormalities, urinary calculi, necrotic papillae, or foreign objects (i.e., urinary catheters, ureteral stents) (Conrad et al, 1991; Richter et al, 2000; Schlager et al, 2001; Abrahams and Stoller, 2003; Kehinde et al, 2004). Identification of the nidus is important, as typically the infection will persist until the source is removed.

Biofilms and Intracellular Bacterial Colonies

Biofilms appear to play a role in bacterial persistence. Biofilms are structured communities of microorganisms encapsulated with a self-developed polymeric matrix and adherent to a living or inert surface (Tenke et al, 2012). Antibiotics that are usually adept at microbial eradication often are unable to eradicate bacteria within a biofilm. The failure of antimicrobial agents to treat biofilms has been associated with the following factors: (1) agents often fail to penetrate the full depth of a biofilm, (2) organisms within a biofilm often grow slowly and are resistant to the antibiotics that usually require active growth, (3) antimicrobial-binding proteins are poorly expressed in these biofilm bacteria, (4) bacteria within a biofilm activate many genes that alter the cell envelope, the molecular targets, and the susceptibility to antimicrobial agents, and (5) bacteria in a biofilm can survive in the presence of antimicrobial agents at a concentration 1000 to 1500 times higher than the concentration normally necessary to kill nonbiofilm-associated bacteria in the same species (Tenke et al, 2006).

Forms of biofilms may allow bacteria to exist both at a bladder and at a kidney level. Within the bladder, bacteria have been seen to invade bladder epithelial cells and to form biofilm-like clusters (IBCs) (Mysorekar and Hultgren, 2006). These will be discussed in greater detail later. In addition, after bacteria reach the kidney, they have been shown to adhere to the urothelium and papillae. In animal models these bacteria can adhere in thin biofilms to the urothelium before invading the renal tissue (Nickel

et al, 1987). It has been further shown that antibacterial agents are less effective against bacteria within these renal biofilms (Nickel et al, 1994).

In addition, biofilms have been shown to form in foreign bodies within the genitourinary tract. These foreign bodies include urinary catheters, ureteral stents, and urinary calculi. Organisms have been shown to ascend through urethral catheters via extraluminal and intraluminal routes. Organisms colonizing the external surfaces of catheters seem to originate from either the gastrointestinal tract or the perineum, whereas intraluminal bacteria appear to come from exogenous sources (Tenke et al, 2012). In fact, it has been shown that 68% to 90% of ureteral stents become colonized with bacteria whereas the rate of bacteriuria in the same patients is only 27% to 30% (Reid et al, 1992; Farsi et al, 1995).

Justice and coworkers (2004) offered possible explanations regarding how the same bacteria may cause recurrent infections without the presence of a nidus or foreign body within the urinary tract. In their work, they showed that after adherence (Fig. 127-5) the bacteria invade the superficial umbrella cells on the luminal surface of the bladder. This occurred within 1 to 3 hours of infection. After invasion, bacterial replication resulted in the loose collection of bacteria within the superficial umbrella cell cytoplasm, forming an early IBC. These bacteria within these IBCs continued to mature, forming an organized community with biofilm-like traits. As early as 12 hours after infection, some bacteria within the IBCs were seen to transform into rod-shaped, motile bacteria that then exited the bladder epithelial cells, presumably resulting in bacteriuria, but they were also found to facilitate the spread and colonization among other bladder cells. Late forms of these IBC bacteria differentiated into filamentous bacteria, which are elongated bacteria, and have the ability to release rod-shaped bacterial daughters that serve as a fresh population of uropathogens that can further invade superficial umbrella cells or disseminate into the genitourinary system. This life cycle, in and of itself, results in the self-perpetuation of bacteria within the bladder.

One host response to infection is that the bladder epithelium undergoes exfoliation in an attempt to rid itself of the bacteria (Mulvey et al, 1998, 2001). However, by developing the ability to invade and divide within the superficial umbrella cells, followed by release from these cells and reinvasion, these bacteria are able to evade this host response and remain within the bladder despite the elimination of these previously infected cells. In addition, Justice and coworkers (2004) further observed that the IBCs themselves can resist the host's immune response. Polymorphonuclear mononucleocytes (PMNs) are known to be rapidly recruited to the bladder and play a major role in clearing extracellular bacteria (Haraoka et al, 1999). It was observed that these PMNs were able to recognize infected versus uninfected superficial umbrella cells. However, the early and middle IBCs provided a safe haven for intracellular bacteria to continue to multiply by delaying the PMN's ability to access and engulf the intracellular bacteria. In addition, after the PMN gained access within the infected umbrella cell, they were unable to clear all of the bacteria. Therefore, a large number of bacteria were able to escape PMN activity. All of this taken together demonstrates how bacteria may establish and develop quiescent reservoirs within the bladder epithelium, and that, despite host immune responses, they might be allowed to persist and potentially result in recurrent infections from the same bacteria. It is important to keep in mind, however, that this work was performed using a murine model. Schlager and colleagues (2009) attempted to identify bacterial reservoirs in patients with neurogenic bladders. They obtained random bladder mucosal samples from 9 patients with neurogenic bladders while undergoing bladder augmentation, urinary diversion, or diagnostic cystoscopy, and they found no evidence of bacterial reservoirs in any of the samples. Clearly this is a small sample size and random bladder biopsies may not have the same yield in finding these reservoirs as compared to bivalving an entire mouse bladder and then examining it, but perhaps IBCs may not have a role in recurrent human UTIs. However, further analysis did show a significant B cell infiltration in the submucosa of patients with neurogenic bladder or VUR (Schlager et al,

Figure 127-5. Urinary tract infection (UTI) pathogenic cascade model. This model depicts the sequence of events during the progression of establishment of a UTI based on the data presented in this report in conjunction with previous studies. The first round of the developmental process (black arrows) directly leads to the second round (magenta arrows) that completes at the time of massive exfoliation of the superficial umbrella cells. At this time, the reservoir is established (orange arrows). Exfoliation of epithelial cells occurs as a mechanism of the innate immune system (gray arrows). Events that lead to recurrence and the mechanism of bacterial growth during recurrence are unclear (red arrows and question mark); these events may include re-entry into the characterized cycle at the point of early intracellular bacterial community (IBC) formation. Bacteria (green) bind to and invade into superficial umbrella cells via type 1 pili (blue). Detachment from IBCs and fluxing out of infected cells likely involve flagella expression. (Modified from Justice SS, Hung C, Theriot JA, et al. Differentiation and developmental pathways of uropathogenic *Escherichia coli* in urinary tract pathogenesis. *Proc Natl Acad Sci U S A*. 2004;101(5):1333–8.)

2011). It was believed that these inflammatory changes might have been secondary to repeated bladder infection.

Bacterial reinfection occurs when a patient suffers a new recurrent UTI caused by a different uropathogen that is based on the documentation of proper urine cultures with each new infection. Often, bacterial persistence may be suspected (rather than reinfection), based on repeated urine cultures demonstrating the same bacterial species, most commonly *E. coli*. These recurrent infections, however, may actually be cases of reinfection rather than persistent occurrences. *E. coli* occurs in multiple serotypes, and careful serotyping of the infecting organisms may actually identify that these are different entities within the same bacterial family, resulting in these recurrent infections (Schlager et al, 2002).

Asymptomatic Bacteriuria

Asymptomatic bacteriuria (ASB) is defined as the presence of two consecutive urine specimens yielding positive cultures ($>10^5$ CFU/mL) of the same uropathogen in a patient who is free of any infectious symptoms (Kass, 1956). It remains unclear why certain individuals with ASB do not develop symptoms, especially because the organisms recovered from their urine are commonly the same as those seen in patients suffering symptomatic UTIs. In fact, the most common organism obtained from these ASB individuals is *E. coli* (Raz, 2003). One possible mechanism is that the organisms infecting these asymptomatic individuals may be less virulent, resulting in colonization rather than infection.

Some have suggested that the term *asymptomatic bacteriuria* is misleading, as some studies have shown that ASB is not always asymptomatic. Gaymans and coworkers (1976) noted that 30% of women in their study who were initially diagnosed with ASB later became symptomatic and required antibiotic therapy. Fur-

thermore, Savage (1975) found that whereas 1.6% of schoolgirls studied suffered from ASB, 60% to 70% of these children actually suffered from lower urinary tract symptoms, as well as daytime and nighttime incontinence that they admitted after careful questioning. Therefore these children with ASB may have actually been symptomatic.

ASB occurs in fewer than 1% of full-term infants and in 3% of premature infants (Edelmann et al, 1973). The identification of bacteriuria in these otherwise asymptomatic children is important as these young children may have few signs and symptoms in the face of an infection, and ASB may actually be a marker of underlying genitourinary disease. Given these issues, these infants should be treated with antimicrobial therapy and also should be imaged to evaluate for any congenital issues that could be leading to bacterial colonization (Whitworth, 1981). ASB occurs in 0.8% of preschool girls and even fewer preschool boys (Siegel et al, 1980). Children in this age group who are without VUR and/or other genitourinary abnormalities do not require antibiotics to clear their bacteria, as they do not appear to be at any risk for recurrent symptomatic infections, renal damage, or impaired renal growth (Sidor and Resnick, 1983).

The annual incidence of ASB in school-age girls ranges from 1% to 2%, although about 5% of all school-age girls are estimated to have ASB by the age of 15 years (Kunin et al, 1964; Meadow et al, 1969; Savage et al, 1969). In these school-age girls, spontaneous resolution occurred in 50% in one study, although the 50% who cleared their infection were found to harbor asymptomatic bacteria 1 year later (Raz, 2003). If these patients were treated with antibiotics at the time of identifying the ASB, 20% had persistent cure, whereas 80% had recurrence and some of these recurrent infections were symptomatic. Girls at this age who are found to have ASB are at very low risk for developing a decline in their renal function or

for developing hypertension (Lindberg et al, 1978; Kunin, 1985). As antimicrobial therapy in these individuals is unlikely to prevent later asymptomatic or symptomatic bacteriuria, and untreated individuals appear to be at low risk of developing long-term sequelae related to the bacteriuria, routine antimicrobial therapy is not recommended. Also, routine prophylactic antibiotics could certainly lead to increased antibiotic resistance in these individuals.

Screening children for ASB is not cost-effective. Kemper and Avner (1992) showed that given the sensitivity and specificity of our screening methods and the prevalence of bacteriuria in asymptomatic children, routine screening would result in 20% false-positives. In addition, they calculated that routine screening would cost \$2.9 million annually. As there is no evidence that detection and treatment of children with ASB prevents long-term consequences, they surmised that routine screening is not cost-effective or warranted.

Bacterial Nephritis

Acute bacterial nephritis occurs as the inflammation from bacterial infection within the kidney begins to spread throughout the kidney in an increasingly suppurative process with heavier leukocytic infiltrate and focal areas of tissue necrosis (Davidson and Talner, 1973). The advanced generalized form of acute nephritis has been termed *acute bacterial nephritis*, whereas the localized form has been called *acute focal bacterial nephritis* or *lobar nephronia* (Lee et al, 1980). In these individuals, clinical signs and symptoms of septicemia are often present (Thornbury, 1991). Computed tomography (CT) findings include global renal enlargement, inflammatory changes in the perirenal fat, and thickening of Gerota fascia (Soulen et al, 1989). On contrast images there may be ill-defined, nonhomogeneous-decreased parenchymal enhancement that typically is wedge shaped (Fig. 127-6).

Pyonephritis

If purulent exudate from APN accumulates in a dilated renal collecting system, pyonephrosis may occur (Thornbury, 1991). This condition commonly occurs in a hydronephrotic kidney secondary to an obstructed urinary outflow. CT findings typically include an enlarged kidney with a grossly dilated collecting system containing higher than usual fluid attenuation.

Acute Renal Abscess

Individuals presenting with a renal abscess often have symptoms similar to patients with pyelonephritis; however in up to 20% of renal abscess cases, the urine culture may be negative (Thornbury, 1991). This diagnosis is usually based on radiographic findings.

Figure 127-6. Computed tomography scan demonstrating lobar nephronia.

Ultrasound can detect an abscess as small as 1 cm in size and usually appears as a sonolucent area containing low-amplitude echoes (Soulen et al, 1989). CT appears to be the most sensitive and specific imaging modality to use in making the diagnosis of a renal abscess. Associated early CT findings include: (1) a well-defined area of low attenuation or decreased enhancement or (2) a striated, wedge-shaped zone of increased or decreased enhancement. In later phases, these areas may coalesce to form a well-defined mass with homogeneous internal attenuation features indicating purulent fluid.

KEY POINTS: CLASSIFICATION

- UTIs may be classified in a variety of ways.
- A UTI is commonly classified as pyelonephritis based on the patient's presenting symptoms, which commonly include fever, flank pain, nausea, and vomiting; however, based on DMSA studies only 50% to 66% of patients with these symptoms demonstrate acute inflammatory changes on their DMSA scan.
- ASB occurs in 0.8% of preschool girls and even fewer preschool boys. Children in this age group who are without VUR and/or other genitourinary abnormalities do not require antibiotics to clear their bacteria, as they do not appear to be at any risk for recurrent symptomatic infections, renal damage, or impaired renal growth.

DIAGNOSIS OF PEDIATRIC URINARY TRACT INFECTION

Defining what constitutes a UTI is surprisingly difficult. Although multiple international guidelines delineate the diagnosis, evaluation, and management of pediatric UTIs, they differ significantly and a consensus is lacking (Mori et al, 2007; Subcommittee on Urinary Tract Infection et al, 2011; Ammenti et al, 2012; Royal Children's Hospital Melbourne, 2011). At the most basic level, a UTI consists of the invasion of the urinary tract by organisms that result in pathologic changes. These pathologic changes may be caused directly by the infecting organism or by the host response to the infectious agent. In most cases, the individual also suffers symptoms from a UTI. To prove that a patient is experiencing a UTI requires a demonstration of the presence of the infecting organism in the urine and a confirmation that this organism is pathogenic. The presence of the infecting organism is routinely proven by urine culture. The presence of pathology within the urinary tract is frequently inferred by symptoms or by evidence of an immune response identified by urine or blood tests. As discussed in the following sections, controversy exists regarding the best method to obtain urine for analysis and culture as well as regarding the results that can be considered indicative of a true UTI.

Symptoms

The classic symptoms in an adult with a UTI, such as dysuria, frequency, urgency, or suprapubic or flank pain, become progressively more difficult to identify with decreasing age in the pediatric population. Symptoms in infants and young pediatric patients are typically nonspecific and include fever, irritability, poor feeding, jaundice, failure to thrive, vomiting, diarrhea, abdominal distention, or foul-smelling urine (Rudinsky et al, 2009; Craig et al, 2010; White, 2011).

Early after the neonatal period, fever is usually the primary symptom that leads to the diagnosis of a pediatric UTI. The overall prevalence of a UTI in febrile infants with no other identified source of fever is about 5% (Hoberman et al, 1993; Haddon et al, 1999). Fever lasting more than 2 days that is greater than or equal to 38°C without an identified source has been shown to have a positive likelihood ratio of 3.6 (confidence interval [CI] 1.4 to 8.8) of being an occult UTI (Shaikh et al, 2007). This likelihood increases with the duration and height of the fever. Although children with pyelonephritis tend to present with fever, as noted previously this is a

nonspecific sign and children with acute cystitis may also present with fever. Older children may complain of more classic symptoms such as dysuria, incontinence, changes in voiding habits, enuresis, or flank or abdominal pain (Shaikh et al, 2007). However, even when these symptoms are present they are nonspecific and, in one series of children aged 2 to 19 years with such symptoms, the prevalence of a UTI was only 7.8% (Shaikh et al, 2008). Other causes of lower urinary tract symptoms are frequently seen in patients with bladder and bowel dysfunction or vulvovaginitis. The lack of specific symptoms produced by a UTI frequently contributes to a lack of prompt diagnosis and treatment; however, the high prevalence of pediatric UTI dictates that it must remain a diagnostic consideration by clinicians caring for children.

Because the specificity of UTI symptoms is lowest in neonates and young children, as is the difficulty in obtaining urine for analysis and culture in this age group, the AAP 2011 guidelines contained an action statement to assist physicians in determining which febrile children between 2 and 24 months of age should be tested for a UTI (Subcommittee on Urinary Tract Infection et al, 2011). This statement recommends that if the clinician believes a febrile infant with no apparent source of fever is not so ill as to require immediate antimicrobial therapy, then the likelihood of UTI should be assessed. If the likelihood of a UTI is low (<1%), then the infant could be followed without urine testing. If the likelihood is higher, urinary evaluation should be considered. The probability of a UTI in girls has been shown to be greater than or equal to 1%, and the probability is 2% if they had two or more, or three or more, of the following risk factors, respectively: white race, age less than 12 months, temperature greater than or equal to 39° C, fever lasting 2 days or more, or absence of another source of infection (Gorelick and Shaw, 2000). The probability of a UTI in an uncircumcised febrile boy between 2 and 24 months exceeds 1% without any other risk factors. In a circumcised febrile boy, the probability of a UTI has been found to be greater than or equal to 1%, and the probability is 2% if they had three or more, or four or more, of the following risk factors, respectively: nonblack race, temperature greater than or equal to 39° C, fever lasting 2 days or more, or absence of another source of infection (Table 127-2) (Shaikh et al, 2007).

In addition to the symptoms previously noted, risk factors for UTI should be elicited, such as a history of a previous UTI. Children younger than 6 years of age with a documented UTI have been noted to have a 12% risk of recurrence per year in a community-based study (Conway et al, 2007). Other risk factors that should be evaluated include the presence of genitourinary anomaly, history of abnormal prenatal or postnatal ultrasounds, family history, and previous genitourinary or gastrointestinal surgery. Such risk factors will increase the probability of a UTI and the need for evaluation of a UTI in an unwell child. They may also point to predisposing conditions that require evaluation and treatment. The possibility of sexually transmitted diseases in older children and adolescents with symptoms of urethritis must be considered. Urethritis can be caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or *Ureaplasma urealyticum* as well as routine uropathogens.

At present, a multicenter diagnostic and prospective observational study (diagnosis of UTIs in young children [DUTY]) is underway and is recruiting 7000 children less than 5 years of age in the United Kingdom to help identify clinical predictors including signs, symptoms, and urine dipstick results that are most strongly associated with a UTI (Downing et al, 2012).

Physical Examination

Specific findings on physical examination in young children are rare and may consist of fever or lethargy. Even if another source of fever and infection such as otitis, upper respiratory infection, or gastroenteritis has been identified, the clinician must keep in mind that a concurrent UTI has not been excluded. It is not unusual for the pediatric urologist to see a child with a history of recurrent episodes of otitis following their first diagnosed UTI with DMSA scan, suggesting that the child had multiple previous episodes of pyelonephritis. The reduction in risk of a UTI when another infec-

From Bitsori M, Galanakis E. Pediatric urinary tract infections: diagnosis and treatment. Expert Rev Anti Infect Ther 2012;10(10):1153-64.

tious source has been identified may be smaller than anticipated, with several studies demonstrating a risk reduction of only about 50% (Bhat et al, 2011). In a study of 2411 febrile 1-year-old children, the prevalence of a UTI without an identified fever source was 5.9%, compared to 2.7% in those with a potential source (Shaw et al, 1998). In this study, the examining clinician incorrectly thought 64% of children with UTI had another source of fever. This highlights the need to consider the possibility of a UTI in any febrile infant, even if another source has been identified.

Both boys and girls should have an abdominal examination to assess for palpable abdominal mass that may indicate bladder distention or a flank mass consistent with hydronephrosis. Older children may experience suprapubic, abdominal, or flank tenderness. Costovertebral angle tenderness is suggestive of pyelonephritis. A careful examination of the external genitalia should be performed to rule out trauma, local irritation, urethral meatal stenosis or discharge, phimosis, foreign body, and anatomic abnormalities. Boys should be examined for testicular tenderness, which may be a sign of epididymo-orchitis. The introitus should be inspected in girls for discharge and signs of local irritation, ectopic ureter, or protruding urethral mass such as a prolapsing ureterocele. Examination of the back for signs of spina bifida occulta such as a prominent fat pad or asymmetric gluteal cleft or sacral dimple, along with a neurologic examination, may point to underlying neurologic causes of abnormal bladder function predisposing to UTIs.

Laboratories

Urine Collection Methods

Because of the nonspecific symptoms and signs, the diagnosis of a UTI requires the demonstration of an infectious agent or agents in

the urine. In addition, the AAP guidelines also require evidence of pyuria for the diagnosis of a UTI to help distinguish a true infection from ASB or contamination. **Unfortunately, the chance of collecting a contaminated urine specimen increases with the decreasing degree of invasive collecting methods.** Different guidelines suggest different methods of collecting urine specimens. The least invasive method of obtaining a urine specimen consists of affixing a collection bag to the perineum. This method has the highest chance of contamination by perineal and rectal flora as well as by white blood cells (WBCs) from outside the urinary tract, producing false-positive results. The urine from a collection bag only provides reliable information when the specimen is normal. A clean-catch midstream urine sample is also noninvasive but carries a higher chance of contamination from periurethral tissues than urine collected via more invasive methods including catheterization or SPA. The clean-catch urine is more reliable in an older girl or a circumcised boy or in an uncircumcised boy who will retract his foreskin compared to a younger girl or an uncircumcised boy who cannot retract the foreskin.

For young, non-toilet trained children less than 2 years of age, the AAP guidelines recommend either SPA or catheterization. The disadvantages of these methods include their invasiveness and the potential for trauma or infection and the fact that they may not be feasible as a routine procedure in primary care. The National Institute for Health and Care Excellence (NICE), Italian Society of Pediatric Nephrology (ISPN), and Royal Children's Hospital (RCH) Melbourne guidelines all recommend a clean-catch urine specimen when possible. Compared to SPA, the clean-catch urine for culture has a sensitivity of 75% to 100% and a specificity of 57% to 100% (Whiting et al, 2006; Bitsori and Galanakis, 2012). Compared to SPA, the catheterized urine has a sensitivity of 95% and a specificity of 99% (Roberts, 2012).

Catheter insertion should be performed in a sterile fashion. The use of intraurethral and/or topical lidocaine has been shown to be effective in reducing discomfort with bladder catheterization (Gerard et al, 2003; Vaughan et al, 2005; Mularoni et al, 2009). Successful catheterization in girls often requires a two-person technique. The labia majora should each be placed on gentle traction outward from the body and slightly lateral to help expose both the vaginal and urethral opening to facilitate the correct location for catheter insertion. This method, as opposed to one using a single hand and fingers spreading the labia laterally, more routinely exposes the normally recessed urethral opening and the surrounding anatomic landmarks. The exposure with this two-hand technique reduces the temptation to pull the labia too far laterally, which may occur with a single hand. Pulling the labia too far laterally can cause pain, making subsequent catheterization far more difficult and traumatic. After catheter insertion, the first several drops of urine obtained from a catheter should not be collected because they may contain urethral bacterial contamination.

The method of suprapubic aspiration involves prepping the skin and inserting a 22-gauge needle 1 to 2 cm above the pubic bone into the bladder and aspirating the urine into a sterile syringe. The reported success rates of obtaining urine by SPA are variable and although not routinely required, ultrasound confirmation of urine in the bladder, as well as guidance during the procedure, have demonstrated improved success rates (Gochman et al, 1991; Buys et al, 1994). Topical or local anesthetic may also be used but data confirming a significant reduction in discomfort with their use are lacking.

Urinalysis

Urinalysis routinely consists of urinary dipstick testing and microscopic examination. A urinalysis specimen should be performed on urine less than 1 hour after voiding if the specimen has been maintained at room temperature or less than 4 hours if refrigerated. Although a urine culture is the gold standard for diagnosis of a UTI, a culture requires at least 18 hours to demonstrate growth and 2 to 3 days to determine the final result and antibiotic susceptibilities. The urinalysis provides rapid information that may be used

to determine the likelihood of a UTI and the appropriateness of beginning antibiotic treatment for a presumed UTI.

Urine Dipstick Tests

The most frequently used dipstick tests for evaluation of UTI include leukocyte esterase and nitrite. Leukocyte esterase is released from white cells that are broken down in the urine and serves as a marker for pyuria. The sensitivity of leukocyte esterase for detecting UTI ranges from 47% to 95% in various studies with a summary estimate of 79% (95% CI 73% to 84%) (Hoberman et al, 1994; Williams et al, 2010). The specificity ranges from 64% to 92%, with false-positives resulting from other causes of inflammation or white cells in the urine (Subcommittee on Urinary Tract Infection et al, 2011). The summary estimate of leukocyte esterase specificity was 87% (95% CI 79% to 91%) in a large meta-analysis by Williams and colleagues (2010). Although it has been estimated by some that the leukocyte esterase test will miss more than 20% of children with a UTI, the AAP guidelines suggest the absence of leukocyte esterase in the urine helps distinguish individuals with ASB from those with a true UTI, as the absence of pyuria in children with a true UTI is rare (Bhat et al, 2011; Subcommittee on Urinary Tract Infection et al, 2011).

Urinary nitrite is reduced from dietary nitrates in the urine by gram-negative enteric bacteria. This conversion requires several hours to occur; thus a first-morning urine has the best sensitivity with this test. Frequent urination, as is often the case in infants and small children, may not permit enough time for the urine in the bladder to undergo significant conversion of nitrates to nitrites and therefore might result in a false-negative nitrite test more frequently than in older children (Mori et al, 2010). A dilute urine may also generate a false-negative test. Other reasons for false-negative tests include infection with gram-positive organisms that do not reduce nitrates. Because of false-negatives, the sensitivity of the nitrite test is about 50%, with a reported range from 8% to 95%. The specificity, however, is very high, at 98%, with a range from 90% to 100%, meaning a positive nitrite test is very likely to reflect a true UTI. In the large meta-analysis by Williams and coworkers (2010) the sensitivity and specificity for nitrites were 49% (95% CI 41% to 57%) and 98% (95% CI 96% to 99%), respectively.

If either leukocyte esterase or nitrite is positive, the sensitivity and specificity for UTI has been reported to be 88% (95% CI 82% to 91%) and 79% (95% CI 69% to 87%), respectively. (Williams et al, 2010). If either of these tests is positive, or the microscopic urine analysis is positive (see later) the sensitivity increases to 99.8% with a specificity of 70% (Subcommittee on Urinary Tract Infection et al, 2011). If both tests are negative, the presence of a UTI is much less likely, with a negative likelihood ratio of 0.22; however, based on the severity of the clinical picture, including a consideration of the patient's age, in many cases the safest course of action might be to continue antibiotics until culture results are available (Perkins et al, 2012). Although not widely used, some have suggested that the addition of the dipstick results for blood and protein to leukocyte esterase and nitrite results improves sensitivity and specificity. Ramlakhan and colleagues (2011) demonstrated that if a sample was negative for all four of these parameters, the sensitivity for ruling out a UTI was 97.4% (95% CI 91% to 99%) and a negative likelihood ratio of 0.10 (95% CI 0.02% to 0.39%). They noted the best test for confirming a UTI was a combination of leukocyte esterase and nitrite and blood, with a specificity of 97.1% (95% CI 94% to 99%) and positive likelihood ratio of 15.13 (6.99 to 32.76).

Urine Microscopic Examination

The traditional method of assessing pyuria by microscopy is on a centrifuged urine specimen with a threshold of 5 WBCs per high-power field (HPF); however, a threshold of 10 WBCs/HPF has been considered more reliable to predict UTI in children less than 2 years old by NICE, ISPN, and RCH Melbourne guidelines (Bitsori and Galanakis, 2012). Williams and coworkers (2010) reported the

sensitivity and specificity of 5 microscopic WBCs/HPF for determining UTI as 74% (95% CI 67% to 80%) and 86% (95% CI 82% to 90%), respectively. The true positive rate for 5 WBCs/HPF and for 10 WBCs/HPF has been reported as 67% (range 55% to 88%) and 77% (range 57% to 92%), respectively. False-positive rates for 5 and 10 WBCs/HPF have been reported as 21% and 11%, respectively (Gorelick and Shaw, 1999). Given the sensitivity and specificity of microscopic pyuria, there does not appear to be an advantage of microscopy for WBCs alone over leukocyte esterase for the determination of UTI, and the additive value of microscopy to dipstick results remains to be definitively demonstrated.

The most reliable rapid test for diagnosing a UTI consists of the microscopic identification of bacteria on both unstained and Gram-stained uncentrifuged fresh urine specimens (Gorelick and Shaw, 1999; Williams et al, 2010). Both the sensitivity and specificity for microscopic bacteria are improved by Gram stain (Subcommittee on Urinary Tract Infection et al, 2011). The sensitivity of microscopic bacteria on Gram-stained samples to determine a UTI is 91% (95% CI 80% to 96%) and on unstained samples it is 88% (95% CI 75% to 94%). The specificity on stained and unstained samples is excellent at 96% and 92%, respectively (Williams et al, 2010). Enhanced urinalysis uses a WBC counting chamber on uncentrifuged urine and uses the microscopy of a Gram-stained urine smear for detection of bacteria, and this improves predictive results but requires the availability of specialized equipment and personnel that are not routinely available in many clinical settings.

Urine Culture

A positive urine culture is essential for the diagnosis of a UTI. The definition of what constitutes a true positive urine culture based on the number of CFU per mL of urine is debated. As with most tests, the lower the threshold is set, the higher the likelihood of obtaining false-positive results and overtreating patients who do not have infection. Conversely, setting a higher threshold increases the chance of undertreating patients. Historically, the threshold used to diagnose a positive urine culture was greater than or equal to 10^5 CFU/mL of a uropathogen. However, this value was initially based on morning-voided urine samples in adult women and this cutoff may not be as applicable in children (Kass, 1962).

Factors that may reduce the concentration of bacteria in the urine of a child with UTI include frequency of urination as well as urine output. At present, there is a lack of uniform agreement on what colony count should be used as the threshold values for the diagnosis of a pediatric UTI. The 2011 AAP guidelines suggest that a reduction from greater than or equal to 10^5 CFU/mL be used in children aged 2 to 24 months. These new guidelines recommend that 50,000 CFU/mL, now including the requirement of a positive urinalysis for pyuria from a urine sample obtained by catheterization or SPA, be used for the diagnosis of UTI. Alternatively, the European Association of Urology suggests that 10^4 CFU/mL is indicative of UTI with a midstream specimen if associated with symptoms, but 10^5 should be used if there are no symptoms (Downing et al, 2012).

Other guidelines have taken into consideration the risk of contamination by various methods of urine collection and their threshold values have been adjusted accordingly. The RCH Melbourne Guidelines suggest that any gram-negative bacteria by SPA and greater than 10^5 CFU/mL by catheterization is consistent with UTI. The ISPN guidelines use greater than 10^4 CFU/mL by catheterization for a catheterized specimen and more than 10^5 CFU/mL for a midstream/clean-catch specimen (Bitsori and Galanakis, 2012).

Contamination is more likely in cases with low colony counts. It is also more likely in cultures with heavy, mixed growth of bacteria. In such cultures, however, one must consider the possibility of the existence of a true UTI along with a contaminated specimen when making treatment decisions. Contamination is also more likely in cultures growing nonpathogenic organisms. Such organisms include *Lactobacillus*, coagulase-negative staphylococci, *Corynebacterium*, alpha-hemolytic streptococci, and *Candida* (Bhat et al, 2011).

Serum Tests

A variety of different serum and urine tests have been evaluated for their ability to differentiate kidney infection in a child with UTI. When bacteria invade the kidney, Toll-like receptor signaling initiates an immune response involving the production of cytokines and chemokines, and urinary levels of interleukin-6 and interleukin-8 may be elevated (Montini et al, 2011). This local response may also be accompanied by a systemic response involving fever, elevated WBC, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and procalcitonin. Fever, ESR, and peripheral WBC count have not been shown to differentiate reliably the upper from the lower UTI (Garin et al, 2007). CRP has reasonable sensitivity but low specificity for diagnosing kidney involvement, limiting its use (Garin et al, 2007; Bhat et al, 2011). Procalcitonin rises in response to bacterial endotoxins, although its exact role in the inflammatory response is unknown. In a recent meta-analysis, procalcitonin was shown to be a more robust predictor compared with CRP or WBC for selectively identifying children who had APN during the early stages of UTI as well as those with late scarring as identified by DMSA scanning (Leroy et al, 2013). The sensitivity and specificity of a procalcitonin level greater than or equal to 0.5 ng/mL for detection of APN were 71% and 72%, respectively, and 70% sensitivity and 50% specificity for late renal scarring. Although the sensitivity and specificity for procalcitonin appear limited, it is possible that combining this information with other clinical and laboratory data will improve identification of individuals with kidney infection and guide subsequent clinical management including radiographic imaging (i.e., DMSA or voiding cystourethrogram [VCUG]).

KEY POINTS: SYMPTOMS AND LABORATORY ANALYSIS

- Symptoms of UTI in infants and young pediatric patients are typically nonspecific.
- Even if another source of fever and infection, such as otitis, or upper respiratory infection, or gastroenteritis has been identified, the clinician must keep in mind that a concurrent UTI has not been excluded.
- Urine from a collection bag only provides reliable information when the specimen is normal because of the high incidence of contamination.
- Guidelines vary in their diagnostic criteria for a UTI.
- Leukocyte esterase has a high sensitivity but a lower specificity. Urinary nitrite has a high specificity but lower sensitivity.

Radiographic Imaging

Controversies with Imaging Strategies

As with many of the other aspects related to pediatric UTI, there is a lack of consensus regarding imaging following a first febrile UTI in children. Part of this controversy relates to a lack of evidence supporting the use of routine imaging in decreasing long-term sequelae of kidney infections, including renal scarring, hypertension, and renal insufficiency or failure (Wennerstrom et al, 2000; Moorthy et al, 2005; Wan et al, 2012). Previously the standard evaluation consisted of an ultrasound and a VCUG. However, despite prevalence rates of VUR of more than 30% in many series of children with a febrile UTI, a lack of proven effectiveness of prophylactic antibiotics in preventing recurrent UTIs or renal scars in children with lower grades of VUR have led many to question the use of obtaining a VCUG in all children after their first UTI. Recommendations vary significantly between guideline committees and various advocates (Table 127-3). The NICE guidelines recommend routinely obtaining an ultrasound in children less than 6 months old, but these guidelines limit it in those more than 6 months to children with either a recurrent UTI or an atypical UTI

TABLE 127-3 Summary of the Five Imaging Recommendations

GUIDELINES	ULTRASOUND	VOIDING CYSTOURETHROGRAM	LATE DMSA SCAN
RCH	Yes	If boys <6 mo and/or positive ultrasonography	No
NICE			
<6 mo	Yes	If positive ultrasonography and/or atypical UTI*	
≥6 mo	If atypical UTI	If children with risk factors†	If atypical UTI* If atypical UTI*
TDA	No	If positive acute DMSA	If positive acute DMSA
AAP	Yes	If positive ultrasonography	No
ISPN	Yes	If positive ultrasonography and/or children with risk factors‡	If positive ultrasonography and/or VUR

*Seriously ill, poor urine flow, abdominal or bladder mass, raised creatinine, septicemia, failure to respond to correct antibiotic treatment within 48 hr, or infection with non-*Escherichia coli* organisms.

†Dilation on ultrasonography, poor urine flow, non-*E. coli* infection, or family history of VUR.

‡Abnormal prenatal ultrasonography of the urinary tract, family history of VUR, septicemia, renal failure, age <6 mo in a male infant, likely noncompliance of the family, abnormal bladder emptying, no clinical response to correct antibiotic treatment within 72 hr, or non-*E. coli* infection.

AAP, Academy of Pediatrics; DMSA, ^{99m}Tc-dimercaptosuccinic acid; ISPN, Italian Society of Pediatric Nephrology; NICE, National Institute for Health and Care Excellence; RCH, Royal Children's Hospital (Melbourne); TDA, top-down approach; UTI, urinary tract infection; VUR, vesicoureteral reflux. From La Scola C, De Mutis C, Hewitt IK, et al. Different guidelines for imaging after first UTI in febrile infants: yield, cost, and radiation. *Pediatrics* 2013;131:e665–71.

as defined by being seriously ill, by poor urine flow, by abdominal or bladder mass, by raised creatinine, septicemia, by failure to respond to treatment within 48 hours, or by infection with a non-*E. coli* organism (NICE, 2013). Conversely, the revised AAP guidelines recommended obtaining a renal ultrasound in all children less than 2 years of age with a febrile UTI, but these guidelines no longer recommend routinely performing a VCUG in these children if the ultrasound is normal (Subcommittee on Urinary Tract Infection et al, 2011). In a rebuttal to the AAP guidelines, the Section of Urology of the AAP noted that the revised guideline was based on conclusions that were premature and represented a misinterpretation of data and did not agree that a VCUG should not be routinely performed (Wan et al, 2012). Rather, they recommended that a VCUG remain as an accepted option at this time. They noted that some children with VUR, most frequently those with higher-grade VUR, do benefit from early detection and treatment that prevents subsequent kidney infection, damage, and loss of function.

Multiple studies now exist evaluating the potential sensitivity and specificity of various imaging guidelines after a first febrile UTI with respect to the identification of children with VUR, APN, or renal scars. One review demonstrated that the NICE and AAP protocols would miss 50% and 61% of children with grades III to V VUR and 62% and 100% of renal scars, respectively (La Scola et al, 2013). Another study demonstrated that the NICE protocol did not work as well in boys compared to girls with respect to negative predictive values (Wong et al, 2010). On the other hand, proponents of the NICE or AAP approaches note that significant numbers of children without high-grade VUR were spared the trauma, radiation exposure, and added expense by not undergoing a VCUG or a DMSA scan. In addition, proponents would note that those children possibly benefiting from the diagnosis of higher grades of VUR would be identified following a recurrent UTI and that prompt diagnosis and treatment of that recurrent UTI further minimizes the relatively low chance of renal damage and sequel in these children.

An alternative approach to imaging the child with a febrile UTI has been termed the *top-down approach* (TDA). Those advocating for a TDA recommend obtaining a DMSA scan in children after their first febrile UTI. By subsequently obtaining a VCUG in only those children with an abnormal DMSA scan, this approach may only miss 15% to 30% of children with dilating VUR; however, it does have a lower specificity than some of the other imaging guidelines (Hansson et al, 2004; Preda et al, 2007; Tseng et al, 2007; La Scola et al, 2013). The NICE guidelines recommend DMSA 4 to 6 months after acute infection for children younger than 3 years with atypical

or recurrent UTI and for children older than 3 years with recurrent UTI. The AAP guidelines do not recommend routine DMSA.

At present, it is fair to suppose that all imaging strategies fall short of the ultimate goal of being able to identify and test only those children that will benefit from the results of these tests. In addition, as with all testing, the clinician must ask if the results will alter the management of the child, and if the answer is *no*, then the test should not be ordered.

Ultrasound

Although the usefulness of obtaining an RBUS in all children with a UTI is questioned, the fact that it is noninvasive, is free from radiation exposure, and is widely available makes its routine use widely accepted for children with a history of UTI. The RBUS is frequently the initial imaging study and it demonstrates abnormalities in about 15% of infants and young children after their first febrile UTI (Subcommittee on Urinary Tract Infection et al, 2011). It is estimated that 1% to 2% of these children will exhibit an abnormality that requires additional evaluation or treatment (Alon and Ganapathy, 1999; Hoberman et al, 2003; Montini et al, 2008). Some suggest that an infant with a febrile UTI and normal prenatal third-trimester ultrasound may forego repeating another renal-bladder ultrasound; however, others report that more than 1/3 of children with a normal prenatal ultrasound will have an abnormality detected on ultrasound following their first UTI (Miron et al, 2007; Juliano et al, 2013). Unless the quality of the third-trimester prenatal ultrasound is known to be excellent, it seems prudent to obtain another ultrasound in infants and young children with a febrile UTI. In children older than several years, relative indications for obtaining RBUS include recurrent febrile UTIs, failure to respond as expected to antibiotic therapy, hypertension, and a family history of renal or urologic disease.

In addition to demonstrating the size, shape, and presence of both kidneys, ultrasound helps screen for previously undiagnosed congenital abnormalities, urinary tract obstruction, hydronephrosis, stones, pyonephrosis, and fluid collections such as renal or perirenal abscesses. If a child is unusually ill or not responding to treatment as expected, the clinician may want to obtain an ultrasound as soon as possible to rule out these conditions, because these conditions would warrant additional urgent interventions. A limitation of obtaining an ultrasound during the acute phase of pyelonephritis is the potential for inflammatory changes and edema to cause false-positive results. The inflammatory changes during the acute phase may cause an overestimation of renal size that may not be reflective of the true baseline size of the kidney. If

the infection and changes are localized, as in a case with an acute focal pyelonephritis (lobar nephronia), they might create the appearance of a mass or tumor. In addition, *E. coli* endotoxin may result in renal pelvis dilation that could be confused for hydronephrosis and lead to unnecessary testing (Subcommittee on Urinary Tract Infection et al, 2011).

Children with VUR and an abnormal renal ultrasound, as defined by the presence of hydronephrosis or a size discrepancy of greater than 1 cm, have been shown to be associated with significantly lower spontaneous VUR resolution rates than those with a normal renal ultrasound (Nepple et al, 2011). As one might expect, children with an abnormal renal ultrasound are more likely to have an abnormal nuclear renal scan. Multiple studies demonstrate a strong correlation between the relative renal volume determined by ultrasound and the relative renal function determined by renal scintigraphy in children (Troell et al, 1984, 1988; Sargent and Gupta, 1993; Adibi et al, 2007; Weitz et al, 2013). However, the ultrasound has relatively poor sensitivity for identifying renal injury or scars compared to nuclear cortical renal scintigraphy, and it may miss more than 10% of renal scars (Christian et al, 2000; Moorthy et al, 2004; Massanyi et al, 2013). Despite this limitation, ultrasound may be useful in screening the children who would be most likely to benefit by further evaluation with DMSA scan.

Some authors question the usefulness of obtaining an ultrasound in all children with a febrile UTI. The NICE guidelines do not recommend obtaining an ultrasound in children between 6 months and 3 years of age after the first febrile UTI unless it is atypical. Part of this questioning is related to the limitations of routine ultrasonography. High-resolution ultrasonography has improved the sensitivity of the ultrasound for detection of acute renal involvement (Morin et al, 1999). It is also widely recognized that renal ultrasound includes a very low sensitivity for the detection of VUR, even with high grades of VUR (Nepple et al, 2011; Juliano et al, 2013; Supavekin et al, 2013; Suson and Mathews, 2014). In one large study of children less than 24 months of age after their first febrile UTI, the ultrasound failed to detect 73% of those patients considered to have urologic abnormalities that would require additional surgical or medical interventions (Wong et al, 2010). Others have demonstrated that a normal ultrasound was not associated with a decreased risk of recurrent pyelonephritis (Juliano et al, 2013).

Voiding Cystourethrogram

VCUG may be performed by the instillation of an iodinated contrast medium into the bladder and imaging with fluoroscopy, or with the instillation of nuclear imaging agents such as technetium-99m pertechnetate. When performed with contrast, the VCUG remains the gold-standard imaging technique for the detection and grading of VUR. Some have suggested that the sensitivity for the detection of VUR is higher with nuclear imaging because of the ability to image the bladder continuously; however, the anatomic resolution and ability for grading is significantly less than the contrast VCUG. Because of the decreased anatomic resolution, many prefer to use a contrast VCUG as the initial method and reserve the radionuclide cystogram for follow-up imaging. The contrast VCUG provides additional information aside from grade that may be significant in evaluating and treating a child with a history of UTI. It provides anatomic information about the bladder such as size and shape and the presence of trabeculations or diverticula. The voiding images, which are an essential component of the standard VCUG, provide information about the function of the urinary sphincters as well as any evidence of urethral obstruction. The images may also be evaluated for the stool pattern that could suggest constipation, which is frequently associated with UTIs and abnormal bladder function. In addition, the images might also demonstrate a spinal defect consistent with spina bifida occulta and might raise the possibility of a tethered spinal cord.

In evaluating the child with UTI, VCUG may be performed as soon as the urine is sterile and the child is asymptomatic and demonstrating typical voiding (Hoberman and Wald, 1999). A negative

VCUG does not completely eliminate the possibility of VUR. One study demonstrated that 30% of patients with a history of VUR and a single negative nuclear VCUG showed positive cystogram results 1 year later (Neel and Shillinger, 2000). A cyclic VCUG, in which the bladder is filled, the child voids, and the bladder is filled a second time and is followed by voiding, will increase the sensitivity for VUR detection as well as the detection of an ectopic ureter. Overfilling of the bladder beyond the expected bladder capacity has also been shown to increase the detection of VUR; however, the physiologic significance of VUR under such artificial circumstances would seem to be minimal and would potentially lead to significant overtreatment. It should be noted that at present there are no widely accepted technical performance standards for a VCUG. Factors such as the size of the catheter, how much contrast should be instilled and at what rate or height/pressure the contrast should be hung, as well as how many cycles should be performed vary significantly among institutions (Palmer et al, 2011).

The radiation reported from VCUG varies from 0.5 to 3.2 millisievert (mSv) with 1 mSv noted as a commonly accepted value (La Scola et al, 2013). One reported advantage of the radionuclide VCUG is lower radiation exposure; however, improved imaging techniques have significantly reduced radiation exposure with fluoroscopic VCUG (Kleinman et al, 1994). To avoid the radiation associated with VCUG, an ultrasound technique has been developed, which is called the voiding cystourethrosonography (Darge, 2010). This technique requires the instillation of sonographic contrast medium via catheter into the bladder, and further investigation remains to be undertaken to determine its sensitivity compared to the VCUG (De Palma and Manzoni, 2013).

^{99m}Tc-dimercaptosuccinic Acid

Cortical renal scan with DMSA combined with single-photon emission computed tomography (SPECT) is considered by many as the gold standard for identification of lesions in the renal parenchyma (Craig et al, 2000; De Palma and Manzoni, 2013). DMSA is injected intravenously and is taken up by the kidney, bound to the proximal renal tubular cells, and excreted very slowly in the urine, providing good and stable imaging of the renal cortex. The imaging is obtained 2 to 4 hours after injection. Of note, it has been shown with CT that DMSA may miss some lesions of APN; however, there are significant drawbacks to using CT in children with UTI (see later) (Lee et al, 2011). The radiation dose for DMSA scintigraphy has been estimated as 1 mSv (La Scola et al, 2013).

The maximum sensitivity of DMSA for detection of APN is within 1 week from the onset of symptoms (Zhang et al, 2014). A DMSA within the first 10 days of APN shows abnormal results in 49% to 79% of patients and this decreased to 30% by 1 month after a UTI (Supavekin et al, 2013). Therefore, the timing of DMSA for detection of kidney involvement with a UTI significantly impacts its sensitivity. Acute DMSA studies usually demonstrate uptake defects in the cortex. In addition, the overall size of the kidney may appear enlarged because of inflammation and edema. Assessment of irreversible renal damage and scar should not be performed earlier than 6 months after APN, and some suggest waiting up to 1 to 2 years for resolution of any reversible defects (De Palma and Manzoni, 2013). Many acute cortical lesions are transient, but about 15% of children with these lesions will develop evidence of renal scarring on repeated DMSA (Shaikh et al, 2010). Renal scars appear as regions of decreased uptake in the cortex, but they may be indistinguishable from regions of congenital renal dysplasia that are frequently associated with VUR.

Multiple studies demonstrate that the risk of an abnormal DMSA is increased in patients with dilating grades of VUR compared to those with nondilating or no VUR (Wong et al, 2010; Supavekin et al, 2013; Zhang et al, 2014). It is this finding that advocates of the TDA cite as advantageous for selecting children with clinically significant VUR to undergo subsequent VCUG. The degree of renal scarring has also been demonstrated to be worse with higher grades of VUR (Shaikh et al, 2010; Supavekin et al, 2013). In addition, abnormal DMSA scan has been demonstrated to decrease the

likelihood of spontaneous VUR resolution independent of the grade of VUR (Nepple et al, 2008a, 2008b; Sjöström et al, 2010). Most studies demonstrate that older children have a higher chance of renal cortical defects, which is a finding that is consistent with the cumulative nature of scars.

In addition to DMSA, other renal nuclear agents such as ^{99m}Tc -mercaptoacetyltriglycine (MAG3) may be used. Although it may not provide quite the level of detailed imaging of the renal cortex that is obtained with DMSA, it does have some advantages. This scan provides renal cortical imaging as well as imaging of the collecting system, which is useful in assessing obstruction of urinary flow. In a very hydronephrotic kidney, imaging of the collecting system may help reduce false-positive results that would be obtained with a DMSA. Because of its uptake and rapid excretion relative to DMSA, the duration of the study and the radiation dose to most organs, including the bladder and gonads, are reduced (Sfakianakis and Georgiou, 1997).

Computed Tomography

Although CT provides detailed anatomic imaging and excellent sensitivity for determination of kidney involvement with infection, the high degree of radiation, as well as potential problems with contrast media, severely limit any benefit of this imaging modality in a child with a UTI. The mean radiation dose for a pediatric abdominal/pelvic CT is 10 to 15 mSv (Miglioretti et al, 2013). One exception may be a noncontrast CT when there is a high index of suspicion for urolithiasis not identified by ultrasound. In addition, it may be useful for distinguishing inflammatory changes from the tumor at times when the acute ultrasound is suspicious for a renal mass. Typical findings associated with renal infection and inflammation include cortical regions of hypoattenuation, wedge-shaped defects, a loss of the corticomedullary differentiation, and striations. Although a renal abscess may show no function, it should be noted that a similar appearance can occur on the acute scans with an acute focal pyelonephritis, and delayed scans may be required to distinguish these entities.

Magnetic Resonance Imaging

MRI provides both excellent anatomic and functional renal imaging. However, the expense and potential need for sedation or anesthesia, as well as a limited availability of the procedure, all restrict the use of routine MRI in the child with febrile UTI. In addition, there is a risk of nephrogenic systemic fibrosis in some patients with impaired renal function related to paramagnetic contrast media (De Palma and Manzoni, 2013).

KEY POINTS: RADIOGRAPHIC IMAGING

- Various conflicting guidelines have been developed for imaging the child with a UTI; however, all fall short of being able to identify and test only those children who will benefit from the results of these tests.
- Ultrasound is noninvasive and free of radiation and is readily available, but it is unreliable at detecting VUR and will also miss some renal scars.
- VCUG is the most reliable method of detecting and grading VUR as well as imaging the bladder and urethra.
- DMSA remains the gold standard for renal cortical imaging and provides relative renal function.

MANAGEMENT OF PEDIATRIC URINARY TRACT INFECTION

Antibiotic Treatment

The goals of acute UTI management include eradicating the infectious agent, preventing renal scarring, and alleviating the child's

symptoms. With successful antibiotic treatment the urine usually becomes sterile after 24 hours (Beetz et al, 2002). As might be expected, early antibiotic treatment of febrile UTI is a significant factor in limiting both renal involvement and subsequent renal scarring (Winter et al, 1983; Smellie et al, 1994; Hiraoka et al, 2003; Doganis et al, 2007). One study of infants and young children with febrile UTI demonstrated that the incidence of acute scintigraphic renal lesions increased from 22% to 59% when the start of antibiotics went from 2 to 3 days from onset of symptoms (Oh et al, 2012). The rate of ultimate scar formation in this series also increased from 11% to 76.5% when the start of antibiotics went from 2 days to 6 days from the onset of symptoms, respectively. The role of anti-inflammatory agents such as dexamethasone or methylprednisolone in reducing renal inflammation and ultimate scar formation has been demonstrated in several studies and is currently under investigation (Pohl et al, 1999; Sharifian et al, 2008; Huang et al, 2011).

Because a UTI frequently presents in young children and neonates with nonspecific symptoms, and a definitive diagnosis based on urine culture may require a wait of 2 to 3 days, the clinician must maintain a high index of suspicion for UTI and must routinely begin antibiotics empirically. Surprisingly, although this empiric decision to begin antibiotics for a presumed UTI should be based on a urinalysis and subsequently confirmed and adjusted based on urine culture results, a review of more than 40,000 outpatient pediatric UTIs suggests that a urinalysis was obtained in only 75% of cases and a urine culture was obtained only a little more than half the time (Copp et al, 2013). This practice may lead either to over-treatment with antibiotics in children who do not have UTIs, or undertreatment and therapeutic delay for those who do have UTIs but have a resistant bacteria requiring a different antibiotic. The indiscriminate use of broad-spectrum antibiotics also leads to increased side effects and bacterial resistance.

Inpatient Versus Outpatient Management

Management of suspected UTI should be based on a combination of factors including likely uropathogen, clinical status, and the reliability of the patient and the family to comply with medical recommendations. Fewer than 1% of patients evaluated for UTI in the outpatient setting require admission (Copp et al, 2011). Infants older than 2 months and nontoxic children with suspected pyelonephritis can be treated as outpatients as long as compliance with and tolerance to oral antibiotics is not an issue (American Academy of Pediatrics, 1999; Hoberman et al, 1999; Hodson et al, 2007; Montini et al, 2007). Most antibiotics result in extremely high urine antibiotic levels relative to serum, and several randomized comparative studies of oral and intravenous antibiotics have demonstrated no significant differences in the time elapsed to clinical improvement or to the prevention of renal scars (Hoberman et al, 1999; Hodson et al, 2007; Montini et al, 2007; Bitsori and Galanakis, 2012).

Hospitalization and parenteral antibiotics might be required based on patient age and clinical status. A febrile UTI in newborns and young infants proceeds more frequently to urosepsis than it does in older children. Positive blood cultures are found in 20% of this age group and this group is also more likely to develop electrolyte abnormalities including hyponatremia and hyperkalemia. For these reasons newborns and young infants require hospitalization and parenteral antibiotics (Beetz et al, 2002; Brady et al, 2010). Indications for hospitalization include infants younger than 1 month of age, and, according to some, younger than 2 or even 6 months of age, toxic presentation or dehydration, intolerance to oral intake, and questionable compliance with antibiotics (Royal Children's Hospital Melbourne, 2011). Neonates require initial hospitalization and full septic evaluation along with parental antibiotics. After the diagnosis is confirmed by urine culture, the parental antibiotics may be changed to oral antibiotics depending on the clinical picture, which would include an improvement in symptoms. Significant clinical improvement including defervescence routinely takes at least 24 hours after

beginning antibiotics (Hoberman et al, 1999). Ninety percent of children will have a normal body temperature within 48 hours of the start of therapy, but if the child is not improving after 48 hours an RBUS should be strongly considered. In addition, if urine culture results are not yet available, consideration should be given to broadening antimicrobial therapy (see [Radiographic Imaging](#)).

Antibiotic Duration

In children, antibiotic treatment lasting 7 to 14 days is recommended for febrile UTI because shorter courses have been proven inferior (American Academy of Pediatrics, 1999; Keren and Chan, 2002; Michael et al, 2003). With severe infections, such as acute lobar nephronia, a longer course of antibiotics of at least 3 weeks is sufficient in most cases (Beetz et al, 2002; Cheng et al, 2006). In many cases, a renal abscess can also be treated with antibiotics; however, a lack of clinical response or resolution may require drainage. With less severe UTI, such as afebrile acute cystitis (lower UTI), a 2- to 4-day course has a reduced rate of recurrence compared

to a single dose or a 1-day course and no significant difference compared to a 7- to 14-day course (Michael et al, 2003).

Antibiotic Selection

If a urine Gram stain was obtained, it might help guide initial empiric antibiotic choice while awaiting urine culture results. *E. coli* remains the most common pediatric uropathogen (>80% of UTIs) (Edlin et al, 2013) (Table 127-4). TMP-SMX and amoxicillin are used in approximately 50% of outpatient UTI visits but these might be poor empiric choices because of high resistance rates of *E. coli* (Table 127-5). Nitrofurantoin or a first-generation cephalosporin is an appropriate narrow-spectrum antibiotic choice for many children with a UTI; however, the age of the child and comorbid conditions should also be considered when selecting antibiotics (Copp et al, 2011; Edlin et al, 2013). Uropathogen prevalence and resistance rates also vary by gender and visit setting as well as by previous exposure to antibiotics, so these factors must be considered when choosing empiric antibiotic therapy. **Empiric treatment of acute**

TABLE 127-4 Uropathogen Prevalence by Gender and Clinical Setting*

ORGANISM	MALE		FEMALE	
	OUTPATIENT	INPATIENT	OUTPATIENT	INPATIENT
<i>Escherichia coli</i>	50% (48-52)	37% (35-39)	83% (83-84)	64% (63-66)
<i>Enterobacter</i>	5% (5-6)	10% (8-11)	1% (1-1)	4% (4-5)
<i>Enterococcus</i>	17% (16-18)	27% (25-29)	5% (5-5)	13% (12-14)
<i>Klebsiella</i>	10% (9-11)	12% (10-13)	4% (4-5)	10% (9-11)
<i>Pseudomonas aeruginosa</i>	7% (6-8)	10% (8-11)	2% (2-2)	6% (5-7)
<i>Proteus mirabilis</i>	11% (10-12)	5% (4-6)	4% (4-4)	2% (2-3)

*Based on national data from The Surveillance Network. Prevalence will vary based on region.

TABLE 127-6 Details of Common Antibiotic Dosing

	DOSE	COMMON SIDE EFFECTS	COMMENTS
ORAL AGENTS			
Amoxicillin-clavulanate	20-40 mg/kg/day in 3 doses	Diarrhea, nausea/vomiting, rash	Contraindicated <6 wk of age
TMP-SMX	6-12 mg/kg/day of TMP in 2 doses	Diarrhea, nausea/vomiting, photosensitivity, rash	
Cefixime	8 mg/kg/day in 1 dose	Abdominal pain, diarrhea, flatulence, rash	
Cefpodoxime	10 mg/kg/day in 2 doses	Abdominal pain, diarrhea, nausea, rash	Contraindicated <3 mo of age or when GFR is <50% or in children with G6PD deficiency
Cefprozil	30 mg/kg/day in 2 doses	Abdominal pain, diarrhea, elevated LFTs, nausea	
Cephalexin	50-100 mg/kg/day in 4 doses	Diarrhea, headache, nausea/vomiting, rash	
Nitrofurantoin	3-5 mg/kg in 2 doses	Nausea, vomiting, bad taste	
PARENTERAL AGENTS			
Ceftriaxone	75 mg/kg/day in 1 dose		Single daily dosing acceptable (Gauthier et al, 2004)
Cefotaxime	150 mg/kg/day divided q6-8h		Single daily dosing acceptable alternative
Ceftazidime	100-150 mg/kg/day divided q8h		
Gentamicin	7.5 mg/kg/day divided q8h		
Tobramycin	5 mg/kg/day divided q8h		
Piperacillin	300 mg/kg/day divided q6-8h		

G6PD, glucose-6-phosphate dehydrogenase; GFR, glomerular filtration rate; LFTs, liver function tests; TMP-SMX, trimethoprim-sulfamethoxazole.

UTI should be based on local/regional antibiograms that are revised and published on an annual basis, because uropathogen prevalence and resistance patterns will vary regionally and will change with time ([Table 127-6](#)). [Table 127-6](#) lists common oral and parenteral antibiotics used for treatment of UTI along with common dosing and side effects.

In addition to *E. coli*, other common gram-negative bacterial uropathogens include *Klebsiella*, *Proteus*, *Enterobacter*, and *Citrobacter*. Gram-positive bacterial uropathogens include *Staphylococcus saprophyticus*, *Enterococcus*, and, rarely, *Staphylococcus aureus*. Neonates and young infants should be covered for *Enterococcus* species when choosing empiric antibiotics because the incidence of infections with this uropathogen is higher in early infancy than at a later age ([Beetz and Westenfelder, 2011](#)). *Enterococcus* is frequently sensitive to ampicillin and first-generation cephalosporins. A combination of ampicillin and a third-generation cephalosporin or aminoglycoside is considered a safe empiric choice for neonates and young infants receiving parenteral therapy. Aminoglycosides may be given in once-daily dosing and should be considered for patients at risk for *Pseudomonas* UTIs such as those with recent exposure to antibiotics or urinary tract abnormalities ([Beetz and Westenfelder, 2011](#); [Bitsori and Galanakis, 2012](#)). Parenteral antibiotics may be converted to oral therapy in most children after several days based on culture results and the child's clinical response, including defervescence.

Most uropathogens are susceptible to narrow-spectrum antibiotic agents such as first-generation cephalosporins and nitrofurantoin. However, nitrofurantoin has poor tissue penetration and should not be used for febrile UTI/pyelonephritis. Nitrofurantoin has also been associated with increased risk of hemolytic anemia in infants less than 3 months of age and should not be used in this population. Similarly, TMP is contraindicated in premature infants and newborns less than 6 weeks of age ([Beetz and Westenfelder, 2011](#)). Empiric broad-spectrum antibiotic prescription is appropriate in children at risk for resistant UTI such as those with a history of previous UTI, recent antibiotic exposure, recent

hospitalization, and presence of genitourinary anomaly ([Allen et al, 1999](#); [Cheng et al, 2008](#); [Paschke et al, 2010](#)). Broad-spectrum antibiotics include broad-spectrum penicillins (antipseudomonal penicillins and β -lactamase/ β -lactam inhibitor combination penicillins), macrolides, fluoroquinolones, second-, third-, or fourth-generation cephalosporins, lincosamides, and carbapenems.

Although fluoroquinolones are highly effective against most uropathogens, bacterial resistance has increased as a result of widespread use. Fluoroquinolones should not be a first-line choice but should be reserved for those with suspected or proven resistant uropathogens such as *Pseudomonas aeruginosa*. In addition, the safety of quinolones in children has been questioned and is under investigation ([Bradley et al, 2011](#)).

MANAGEMENT OF POST-URINARY TRACT INFECTION

Following treatment of initial UTI, management is aimed at preventing subsequent UTIs. Routinely repeating a urine culture in children treated with an antibiotic based on previous urine culture susceptibilities is not necessary ([Currie et al, 2003](#); [Oreskovic and Sembrano, 2007](#)). Approximately 10% to 30% of children will develop at least one recurrent UTI ([Winberg et al, 1975](#); [Nuutinen and Uhari, 2001](#); [Shaikh et al, 2008](#); [Peters et al, 2010](#)). The recurrence rate is highest within the first 3 to 6 months following a UTI, and the more frequent and more recurrent a child's UTIs, the more likely he or she is to experience a subsequent UTI ([Winberg et al, 1974](#); [Kasanen et al, 1983](#); [McCracken, 1984](#)). For boys younger than 1 year of age, 18% will develop a recurrent infection, usually within the following year. If the initial infection is in a boy more than 1 year of age, his risk of a reinfection increases to 32%. A similar trend is noted in girls less than and greater than 1 year of age, who have a recurrence risk of 26% and 40%, respectively ([Winberg et al, 1974](#)).

Parents should be counseled regarding the high risk of recurrent UTI and should be urged to seek prompt evaluation for

subsequent febrile illnesses, as prompt treatment from the time of onset of symptoms should help to reduce renal damage. Renal scarring increases with an increasing number of febrile UTIs, with the risk going from 5% to 10%, 20%, 40%, and 60% after the first, second, third, fourth, and fifth pyelonephritic episodes, respectively (Jodal, 1987). Children who have had a febrile UTI should routinely have their height, weight, and blood pressure monitored by their primary care provider.

Identification of the risk factors predisposing a patient to UTIs helps direct individualized patient management by treating or eliminating these risk factors. UTIs, like infections in other sites of the body, are more likely to occur with increased inoculum and duration of exposure to the pathogen as well as in situations that compromise local and/or systemic immunity. Relative to UTIs, factors thought to increase the inoculum and duration of exposure include those that create urinary stasis as well as constipation. Surgical correction of obstructive uropathies should help reduce stasis. Infrequent voiding and urinary retention, or high pressures as may occur with dysfunctional voiding or obstructive uropathies, may compromise the local immunity of the bladder. As noted, a history of a recent UTI also predisposes the child to subsequent UTIs. In some patients, the risk factors responsible for recurrent UTIs may not be identifiable or modifiable, and these patients may benefit from nonspecific preventive therapies.

Prophylactic Antibiotics

The use of prophylactic antibiotics may be considered a nonspecific approach to the prevention of recurrent UTIs. The efficacy of prophylaxis has been questioned, even in children with VUR, by several relatively small randomized series including children with low grades of VUR (Garin et al, 2006; Montini et al, 2008; Pennesi et al, 2008; Roussey-Kesler et al, 2008). Neither the AAP guidelines nor the NICE guidelines recommend routinely prescribing prophylactic antibiotics to infants and children following their first UTI. As might be expected, the benefit of prophylactic antibiotics is more easily demonstrated when used in specific populations known to be at high risk for recurrent UTI (Brandström et al, 2010a). In populations known to be at higher risk for recurrent UTI, such as girls with dilating VUR (i.e., greater than or equal to grade III), prophylactic antibiotics have proven effective (Craig et al, 2009; Brandström et al, 2010a). The following risk factors are associated with a low risk of recurrent UTI and therefore make it more difficult to demonstrate any benefit of prophylactic antibiotics: circumcised boys, no bowel or bladder dysfunction, no recent history of UTI, normal renal ultrasound or DMSA scan, a lack of anatomic abnormalities, and nondilating VUR (Peters et al, 2010). The prospective randomized intervention for vesicoureteral reflux (RIVUR) trial compared TMP-SMX prophylaxis to placebo in 600 children with grade I-IV VUR following UTI and demonstrated that those receiving prophylaxis had a significantly reduced risk of recurrent UTI. The risk reduction for recurrent UTI was greatest in those children with bowel and bladder dysfunction at baseline, a history of febrile UTI, or higher grades of VUR (RIVUR Trial Investigators et al, 2014).

Aside from a lack of efficacy, antibiotic resistance is another concern regarding the use of prophylactic antibiotics. Multiple studies confirm that exposure to antibiotics increases the likelihood that any subsequent UTIs will be caused by bacteria resistant to the previously prescribed antibiotics (Allen et al, 1999; Conway et al, 2007; Craig et al, 2009; Brandström et al, 2010a; Paschke et al, 2010). This relates to the fact that the fecal flora frequently becomes resistant to the treatment antibiotic. In general, the risk of resistance appears to be about 3 times greater following treatment with antibiotics. Thus, the prophylactic antibiotic chosen should be different than the therapeutic antibiotic used for the UTI.

The ideal antibiotic for prophylaxis would be effective against most uropathogens, be easily administered and tolerated without significant side effects, have high urinary concentrations and low serum concentrations, and make little impact on indigenous

bacterial flora and bacterial resistance (Beetz and Westenfelder, 2011). The dosage is usually one fourth the normal dose, and in toilet trained children it is routinely administered shortly before going to sleep in hopes of increasing the duration of antibiotic within the urinary bladder. Common choices for prophylactic antibiotics include TMP-SMX, TMP, nitrofurantoin, and first-generation cephalosporins. With increasing resistance of *E. coli* to TMP-SMX, its use in this manner is increasingly questionable. Sulfonamides may compete for bilirubin binding sites on albumin and cause neonatal hyperbilirubinemia and kernicterus, so TMP-SMX is avoided during the first 6 weeks of life.

Nitrofurantoin produces minimal effect on the fecal flora, and resistance rates have remained relatively low, making it an effective prophylactic antibiotic. Because serum levels with nitrofurantoin are low, it is not recommended for use with APN or urosepsis. In addition, it can cause hemolysis in children with glucose-6-phosphate dehydrogenase (G6PD) deficiencies by oxidizing hemoglobin to methemoglobin. This deficiency is found in about 1 0% of African-Americans, Sardinians, non-Ashkenazi Jews, Greeks, Eti Turks, and Thais. Long-term treatment has been associated with rare cases of pulmonary fibrosis.

Many unanswered questions exist regarding not only which patients benefit from prophylactic antibiotics but also the best therapeutic regimen. The ideal dosing and schedule, as well as the use of alternating antibiotics, remain to be defined. Patient non-compliance with a prescribed daily antibiotic is common, as demonstrated in a study by Daschner and Marget (1975) in which only about one third of children took the prescribed antibiotics on a regular basis and 19% did not take them at all.

Cranberry juice has been suggested to reduce UTIs. A meta-analysis that included adults and children demonstrated no UTI reduction for those using cranberry products as compared to placebo, water, or no treatment (Jebson and Craig, 2012). Several studies in children with neurogenic bladders also demonstrated no reduction on recurrent UTI (Foda et al, 1995; Schlager et al, 1999). However, several other studies in children did suggest a possible benefit of cranberry juice in reducing recurrent UTIs (Ferrara et al, 2009; Salo et al, 2012). At present, there does not appear to be enough evidence demonstrating conclusive benefit to warrant a recommendation for the routine use of cranberry juice or cranberry products in children for the prevention of UTIs.

Circumcision reduces the risk of UTIs in infants and toddlers (Wiswell et al, 1985). The risk reduction appears greatest in those with a history of recurrent UTIs and dilating VUR (Singh-Grewal et al, 2005). Some consider conditions that place boys at high risk for UTI as a relevant medical indication for circumcision. Such patients may have a history of recurrent febrile UTIs, obstructive uropathy, hydroureteronephrosis, or high-grade VUR. The benefit of prophylactic circumcision even in these patients is controversial.

Bladder and Bowel Dysfunction

Consideration and assessment of underlying bladder or bowel dysfunction as predisposing factors should occur with any pediatric UTI. There exists a well-recognized association between bladder dysfunction and UTI, and bladder dysfunction predisposes children to recurrent UTI and renal injury (Nijman, 2000; Hoebeke et al 2001). In particular, the risk of bladder colonization and UTI is increased in children with incomplete bladder emptying resulting from dysfunctional voiding or underactive bladder. In addition, there is an association between VUR and bladder dysfunction (Koff et al, 1998; Schulman et al, 1999; Hoebeke et al, 2001). It is thought that voiding against a closed sphincter can increase bladder pressure and may contribute both to the development and to the persistence of VUR (Yeung et al, 1998, 2006; Chandra and Maddix, 2000). Treatment of bladder dysfunction, particularly overactive bladder, has been shown to improve the spontaneous VUR resolution rate, further suggesting an etiologic component for overactive bladder in the genesis of reflux (Homsy et al, 1985; Koff et al, 1998; Willemssen and Nijman, 2000).

Anorectal and lower urinary tract function are interrelated, and constipation is often associated with bladder dysfunction. Reported frequency of constipation associated with pediatric bladder dysfunction ranges from 30% to 88% (O'Regan et al, 1986; Schulman et al, 1999; Burgers et al, 2013a, 2013b). This relationship between abnormal bowel and bladder function is referred to as bowel bladder dysfunction (BBD) or as the dysfunctional elimination syndrome (DES) (Koff et al, 1998; Feng and Churchill, 2001; Bower et al, 2005; Burgers et al, 2013b). Children with VUR and bowel and/or bladder dysfunction are at particularly high risk for developing recurrent pyelonephritis (Thompson et al, 2001; Hellerstein and Nickell, 2002; Leslie et al, 2010; Sillen et al, 2010). Recurrent UTI are estimated to occur in about 45% of these children as opposed to 15% without BBD (Peters et al, 2010). Treatment of constipation has been shown to reduce recurrent UTIs significantly and to improve bladder function (Loening-Baucke, 1997; Erickson et al, 2003).

Detailed information regarding treatment of pediatric bladder and bowel dysfunction is reviewed in Chapters 143 and 144. In general, the initial conservative therapeutic measures for treating the child with bladder dysfunction include voiding behavior modification with timed voiding schedules and treatment of constipation, if present (Erickson et al, 2003; Allen et al, 2007). In patients who fail conservative treatment, directed therapy is focused toward improving the specific cause of bladder dysfunction. In most cases, noninvasive uroflow studies and the determination of postvoid residual provide enough data to help direct therapy, but some children will benefit from further evaluation with formal urodynamic study. Targeted interventions may include pharmacologic therapy, biofeedback, electrical stimulation therapy, surgery, clean intermittent catheterization, or a combination of these therapies (Nelson et al, 2004; Van Arendonk et al, 2006a, 2006b; Malm-Buatsi et al, 2007). The choice of therapeutic interventions is also impacted by the underlying condition and severity of symptoms. For children with a neurogenic bladder on intermittent catheterization, increasing the frequency of catheterization has been associated with decreased rates of recurrent UTI.

Management of Vesicoureteral Reflux

Sterile VUR does not appear to cause renal injury, although it is now well recognized that it is associated with congenital dysplasia in the kidney. Regions of renal dysplasia demonstrate no function on a DMSA scan and may be identical in appearance to nonfunctional regions from a renal scar caused by UTI. A lack of recognition of the etiology of these areas as dysplasia, and not as scar, previously led to an overestimation of potentially preventable renal injury in all children with VUR by preventing UTI or surgical correction.

Despite the historical overestimation of VUR based on a child's risk of pyelonephritis and renal scars, it is important to note that VUR remains a risk factor for both recurrent pyelonephritis and renal scarring. The risk of both of these events increases with increasing grades of VUR and seems to become significant in most series with dilating VUR (i.e., \geq grade III) (Hellerstein and Nickell, 2002; Conway et al, 2007; Montini et al, 2008; Roussey-Kesler et al, 2008; Brandström et al, 2010a, 2010b; Holmdahl et al, 2010; Leslie et al, 2010; Shaikh et al, 2010; Oh et al, 2012). Intuitively, increasing grades of VUR lead to increases in bacterial inoculum and exposure to the kidney from bacteria in the bladder. Higher grades of VUR also add an element of urinary stasis and decreased mechanical washout of bacteria that likely contributes to an increased exposure of the urothelium to bacteria. At present, the only method to diagnose and grade VUR definitively and to characterize further this risk factor remains the VCUG. As previously noted, multiple studies have challenged the dogma that all children with a febrile UTI and reflux will benefit from the diagnosis of VUR and subsequent treatment of this condition by either continuous antibiotic prophylaxis or surgical correction (Reddy et al, 1997; Cooper et al, 2000; Thompson et al, 2001; Hellerstein and Nickell, 2002; Garin et al, 2006; Montini et al, 2008; Pennesi

et al, 2008; Roussey-Kesler et al, 2008; Leslie et al, 2010; Subcommittee on Urinary Tract Infection et al, 2011).

Almost paradoxically, as more studies provide additional information regarding VUR, determining the ideal management of a patient with VUR has become increasingly complex. It is apparent that risk factors for developing recurrent UTI and renal scars must be considered when evaluating the potential benefits of various treatment options. A child who has VUR and has a negligible risk of developing a recurrent febrile UTI is unlikely to benefit from daily antibiotics. In assessing risk, it is important to treat each patient as an individual needing personalized treatment. Because multiple factors affect an individual's risk, it is not possible to provide excellent health care by developing broad, sweeping guidelines that dictate management protocols based on one specific factor, such as grade of reflux. Rather, one must consider additional information, aside from grade of reflux, gender, and age, ultimately to provide tailored management. The patient's history, presenting symptoms, bowel or bladder dysfunction, likelihood of persistent VUR, and kidney status including function and scars should all be considered and factored into the determination of a child's individual risk for developing recurrent febrile UTIs and renal scars (Cooper, 2012). In addition to considering these factors, the physician must also consider the social situation of the child, which, although difficult to quantify, may be one of the greatest predictive factors for a child's risk of adverse outcome. Guidelines published by the American Urological Association are relatively nonprescriptive, and they permit a wide range of management options for most children with VUR (Peters et al, 2010). These options include observation, continuous antibiotic prophylaxis, endoscopic injection, or open operative correction.

SEQUELAE OF PEDIATRIC URINARY TRACT INFECTIONS

Renal Scarring

Pyelonephritic scarring occurs most commonly in the poles of the kidney and is associated with compound papillae (Hannerz et al, 1987). These papillae are fused with adjacent papillae and contain papillary ducts that open at right angles rather than oblique angles, permitting more pyelotubular backflow of bacteria (Ransley and Risdon, 1974). Children with pyelonephritis and VUR are at increased risk for renal scar development, and this risk increases with increasing grade of VUR (Oh et al, 2010; Shaikh et al, 2010; Lee et al, 2012). After the acute inflammatory phase, the ultimate scar involves a loss of tissue that is reflected on radiographic imaging as thinning of the renal parenchyma over the calyces. The calyces themselves may become blunted and deformed. As noted previously, it can be difficult or impossible to distinguish scar from regions of congenital dysplasia by radiographic imaging, although patients with a small kidney and diffusely decreased isotope uptake and decreased differential renal function are often considered to have renal dysplasia. Although it has been suggested by some that infants and young children have a higher incidence of developing a renal scar following pyelonephritis, conflicting data exist on this topic. Prompt antimicrobial treatment decreases the chance of permanent renal damage, as does the elimination of any subsequent episode of pyelonephritis. The use of anti-inflammatory agents to minimize renal injury and scar during the acute phase of pyelonephritis is under investigation (Pohl et al, 1999; Sharifian et al, 2008; Huang et al, 2011).

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a specific form of chronic inflammatory kidney disease rarely seen in children that is usually associated with an element of obstruction and, most commonly, *Proteus* or *E. coli* (Rippentrop et al, 2002). Symptoms are often vague and nonspecific and may include fever, abdominal or flank pain or mass, and more nonspecific symptoms including weight loss and failure to thrive. Laboratory studies may demonstrate leukocytosis, anemia, and pyuria.

Imaging may demonstrate a mass-like lesion with focal or diffuse renal involvement as well as perinephric extension (Malek and Elder, 1978; Eastham et al, 1994; Cooper and Turner, 1997). This may be mistaken for a malignancy and requires a high index of suspicion (Nam et al, 2012; Inouye et al, 2013). CT images may demonstrate areas of low attenuation that do not enhance as well as dilated calyces. Renal calculi are present in 38% to 70% of patients (Anhalt et al, 1971; Malek and Elder, 1978).

Nephrectomy is the treatment of choice for the diffuse form, whereas partial nephrectomy or conservative medical therapy may be indicated to manage focal XGP (Cooper and Turner, 1997; Nam et al, 2012). Technically, these operative cases can be extremely difficult as the process may extend beyond the kidney, distorting and destroying normal anatomy as it involves and encases surrounding structures including the psoas muscle and, at times, even the great vessels (Malek and Elder, 1978; Loffroy et al, 2007).

Long-Term Sequelae

It is difficult to predict which children will develop long-term sequelae of pediatric UTI, including hypertension, preeclampsia, or chronic kidney disease (CKD), because of a lack of clear data establishing the long-term consequences following pediatric UTIs. A review of 23 papers including a total of 3573 children demonstrates that the majority of children with a history of febrile UTI develop no long-term sequelae (Toffolo et al, 2012). This seems to be true in particular if at birth the children had normal kidneys that were unaffected by significant renal dysplasia. Toffolo and colleagues estimated that only 0.4% of children with normal renal function at the start of follow-up experienced a decrease in renal function. This rate is consistent with that found in the prospective International Reflux Study in Children (Smellie et al, 1998) and in another series of 226 adults with a history of childhood UTI who were followed for 10 to 41 years, which noted that only two patients developed CKD that was attributed to UTIs (Jodal et al, 2006). Wennerstrom and coworkers (2000) demonstrated a decrease in mean GFR after 16 to 26 years of follow-up more frequently in children with bilateral renal scars but not unilateral scars compared to children without scars. This same group showed no significant difference in mean 24-hour ambulatory blood pressure between those with and without urographic renal scars. Two other studies with follow-up of 22 and 41 years demonstrated an increased prevalence of hypertension of 29% and 35%, respectively, in patients with scars, suggesting that scars are a risk factor for the development of hypertension (Jacobson et al, 1989; Bailey et al, 1992). The risk of hypertension appears to increase with the severity of renal scarring. It has also been demonstrated that during first pregnancies, hypertension was significantly more common in women with severe renal scarring (Martinell et al, 1996; Smellie et al, 1998).

Children with significant bilateral renal scars or reduction of renal function warrant long-term follow-up for assessment of hypertension, renal function, and proteinuria. Studies suggest that proteinuria may not only be a clinical feature of CKD but may hasten its progression. The use of renin-angiotensin antagonists may slow the progression of CKD in some of these patients (Wong et al, 2009).

UNCOMMON PEDIATRIC URINARY TRACT INFECTIONS

Viral Cystitis

Acute hemorrhagic cystitis in children has occasionally been related to UTIs caused by adenovirus-11. In a series from Mufson and coworkers (1973) that evaluated children suffering from hemorrhagic cystitis, adenovirus-11 was recovered from the urine in 14.5% of patients, adenovirus-21 was found in the urine of 9% of these children, and *E. coli* was present in 17.4% of the cohort. In the vast majority of the individuals, no infectious etiology was identified.

Viral cystitis has commonly been identified in individuals after bone marrow transplantation and in other immunosuppressed individuals. Without successful treatment, severe viral cystitis and

KEY POINTS: MANAGEMENT AND SEQUELAE

- Delay in antibiotic treatment of a febrile UTI increases the incidence of renal parenchymal involvement and ultimate scar formation.
- Newborns and young infants should be hospitalized because of a higher incidence of urosepsis than older children.
- A total of 7 to 14 days of antibiotic treatment is recommended for children with febrile UTI; a 2- to 4-day course is acceptable for afebrile cystitis.
- Empiric antibiotic selection should be guided by local/regional antibiograms because of changing uropathogen prevalence and resistance patterns.
- Nitrofurantoin should not be used for febrile UTI/pyelonephritis.
- A total of 10% to 30% of children will develop at least one recurrent UTI.
- Antibiotic prophylaxis has been demonstrated to decrease subsequent UTI in high-risk populations such as girls with dilating reflux.
- Bowel and bladder dysfunction increase the risk of recurrent UTI and should be evaluated and treated in any child with a UTI.
- Although the risk of long-term sequelae of pediatric UTIs is relatively low, children with significant bilateral renal scars or a reduction of renal function warrant long-term follow-up for the assessment of hypertension, renal function, and proteinuria.

associated hemorrhagic cystitis is associated with a 50% to 80% mortality rate in these children (Gavin and Katz, 2002). BK virus, a DNA virus of the polyomavirus genus, has also been found in the urine of immunosuppressed and especially bone marrow transplant patients, causing both symptomatic and asymptomatic infections (Apperley et al, 1987; Bedi et al, 1995).

Funguria

Fungal UTIs appear to be increasing in prevalence and are commonly associated with individuals who have recently received antibiotics or who have had indwelling urethral catheters. In one neonatal intensive care unit, funguria increased tenfold throughout a 10-year period (Kossoff et al, 1998). Predisposing factors in children include antibiotic use, prematurity, intravenous and umbilical artery catheterization, parental nutrition, and an immunocompromised state (Keller et al, 1977). The urinary tract may serve as a portal of entry and as a site of disseminated fungal infection. In children with disseminated candidiasis, the kidney is the most commonly involved organ (Keller et al, 1977). *Candida* species are the most common cause of fungal UTI, with *Candida albicans* being the most common species involved in these infections, followed by *Torulopsis glabrata*. It is important to recognize the infections caused by *Torulopsis glabrata*, as these are commonly resistant to fluconazole (Kauffman et al, 2000).

Fungal bezoars may also form in the renal pelvis and potentially create urinary obstruction in these children (Keller et al, 1977; Bartone et al, 1988). For this reason, renal ultrasound may be beneficial in evaluating these patients, especially if the funguria is persistent. Urinary alkalization and oral antifungal therapy may occasionally dissolve some fungal balls, but if the child is suffering from renal obstruction, percutaneous or surgical removal of these fungus balls is necessary. Percutaneous drainage may also be needed so that local antifungal therapy can be administered. In these individuals, local and systemic amphotericin B and/or oral fluconazole may be useful for treatment. If the fungal balls are shown to persist, endoscopic or open surgical removal may be necessary.

Deciding when to treat asymptomatic funguria that are related to indwelling urethral catheters continues to be debated. In individuals with funguria secondary to these foreign bodies,

progression to disseminated candidemia is rare (Kauffman et al, 2000). When repeated urine cultures grow greater than 10,000 to 15,000 CFU/mL, antifungal treatment is generally recommended. Stopping antibiotic therapy, changing or removing urethral catheters, and urinary alkalization may be helpful in some cases, but these do not always clear the fungus from the urine. Prospective studies with intravesical amphotericin B bladder irrigation and oral fluconazole show that both may clear the funguria (Gubbins et al, 1994, 1999). Fluconazole has been used successfully in children, although its use is contraindicated in children less than 6 months of age.

Growth and Maturation

Perioperative Fluids

Pediatric Anesthesia and Analgesia

Surgical Preparation and Intraoperative Considerations

Postoperative Care

The maxim “children are not small adults” is a critically important concept that must be remembered when contemplating surgical intervention in the pediatric population. Children have unique anatomy, physiology, and emotional and psychological needs, all of which vary with the child’s age. In addition, we are increasingly involved in prenatal counseling and care, and therefore an understanding of fetal development and physiology is necessary. This chapter reviews the core principles of pediatric perioperative care, with which any pediatric surgeon must be familiar to ensure optimal surgical outcomes.

GROWTH AND MATURATION

Prematurity and Intrauterine Growth Restriction

A baby born before 37 weeks’ gestation is considered premature. The severity of prematurity may be indicated by the birth weight, although these two factors are not necessarily related. Infants weighing 2500 g or less at birth are considered low birth weight (LBW) in prematurity, but in an infant born full term this weight would indicate intrauterine growth restriction (IUGR). This is an important distinction because full-term neonates with IUGR usually have different problems than premature infants. In the United States, approximately 30% of LBW infants are born after 37 weeks’ gestation. Premature infants weighing 1500 to 2500 g are referred to as moderately low birth weight (MLBW), less than 1500 g are referred to as very low birth weight (VLBW) infants, and infants who weigh less than 1000 g are considered extremely low birth weight (ELBW) infants. MLBW infants account for 82% of premature infants, VLBW 12%, and ELBW 6%. In 2006, 12.8% of live births in the United States were premature, and 8.3% were LBW. Between 1996 and 2006, the rate of premature births in the United States increased more than 16%. With respect to race, the rate of prematurity in the United States is highest for black infants (18.3%), followed by Native Americans (14.1%), Hispanics (12.1%), whites (11.6%), and Asians (10.7%). **The clinical implications of prematurity are profound, and premature infants accounted for 16.6% of all infant deaths in the United States in 2005.** These implications are especially relevant to the VLBW and ELBW infants, who are surviving in increasing numbers because of remarkable advances in neonatal critical care. These infants account for a large proportion of neonatal deaths and long-term disability, and because of their extreme prematurity they are predisposed to hyaline membrane disease, chronic lung disease, retinopathy of prematurity, intraventricular hemorrhage, and necrotizing enterocolitis (Teitelbaum and Coran, 2003b; Pierro et al, 2006; Eichenwald and Stark, 2008; Goldenberg et al, 2008).

IUGR is defined on prenatal ultrasonography as a fetus whose estimated weight is below the 10th percentile for its gestational age. At term, a birth weight below 2500 g is considered a result of IUGR. Approximately 70% of infants with a birth weight that

qualifies for IUGR are constitutionally small, and in the remaining 30%, the cause of IUGR is pathologic. IUGR can be temporary, with a normal-sized baby at birth. General causes of IUGR include placental insufficiency, chronic maternal disease, abnormal placentation, genetic disorders, malformations, immunologic diseases, maternal infections, metabolic diseases, maternal substance abuse, and multiple gestations. IUGR is typically classified as symmetrical or asymmetrical. Symmetrical IUGR describes a fetus whose entire body is proportionally small, and this is considered the more severe form (Styne, 2004). Asymmetrical IUGR is related to processes that require the fetus to direct its energy to the maintenance of vital organs, usually the heart and the brain. Therefore the fetus with asymmetrical IUGR typically has a normal head circumference but a small abdominal circumference, small limbs, reduced skeletal muscle mass, and decreased subcutaneous and abdominal fat. Infants with asymmetrical IUGR more frequently exhibit catch-up growth than their symmetrical IUGR counterparts. However, of all infants with IUGR, 10% to 30% will have short stature as adults. Given the wide variety of causes, the management of IUGR is individualized and complex decisions are often required, weighing elective preterm delivery and the risks of prematurity against the risks associated with IUGR (Teitelbaum and Coran, 2003b; Pierro et al, 2006; Alberry and Soothill, 2007; Goldenberg et al, 2008).

Intrauterine Growth and Lung Development

Proper intrauterine growth and development are dependent on presence of normal amniotic fluid volume. Of particular relevance to urologists is lung development, which is dependent on amniotic fluid. Early in pregnancy, the placenta produces amniotic fluid. **At 10 to 12 weeks’ gestation, the fetal kidneys begin to produce urine, which from there onward comprises the majority of amniotic fluid.** Lung development is a highly complex orchestration of molecular processes, and it is divided into three stages: the embryonic, the fetal, and the postnatal or alveolar stages.

The embryonic stage begins with a ventral bud from the foregut at 3 weeks’ gestation. By 6 weeks, the lung bud divides sequentially into bronchopulmonary segments. These segments are poised for further division, and their embryonic components will ultimately differentiate into specialized epithelium, smooth muscle, cartilage, connective tissue, and blood vessels (Teitelbaum and Coran, 2003b; Wilson and DiFiore, 2006).

The fetal stage of lung development begins at 7 weeks’ gestation and proceeds to term. This stage is further subdivided into three phases: pseudoglandular (7 to 17 weeks), canalicular (16 to 25 weeks), and saccular (25 weeks to term). The pseudoglandular phase is of particular interest, as its timing coincides with the replacement of placenta-derived amniotic fluid with fetal urine-derived amniotic fluid. **By the end of the sixteenth week of gestation, all lung branching occurs resulting in the terminal bronchial airways.** After this time the only further growth that

occurs is elongation and widening of existing airways. A large body of experimental data indicates that these early and critical events in lung development are dependent on lung fluid dynamics, and any restrictive process including tracheal occlusion (e.g., atresia) or oligohydramnios results in pulmonary hypoplasia, which can be fatal at birth. The severity of the restrictive process is proportional to the degree of hypoplasia (Teitelbaum and Coran, 2003b; Wilson and DiFiore, 2006).

Postnatal Considerations

In the postnatal period, growth and development in children occurs at a rapid pace, especially in early childhood. A full-term newborn grows at a rate of 25 to 30 g/day during the first 6 months of life, leading to a doubling of the birth weight during this period. In the first 12 months of life, an infant's birth weight is typically tripled. By 3 years of age, birth weight is expected to quadruple, and by 10 years of age it will increase twentyfold from the birth weight. Body length increases by approximately 50% in the first year of life, and by threefold by 10 years of age (Teitelbaum and Coran, 2003c).

Cardiovascular

A detailed description of pediatric cardiovascular physiology and management is beyond the scope of this chapter, but a few principles are important for the urologist to consider. These include the basic differences between pediatric and adult cardiovascular physiology and an understanding of the common congenital heart defects that may affect our patients.

Compared with the adult heart, the neonatal and pediatric myocardium is stiffer and less compliant. This results in diminished preload reserve, which means that the point at which further increases in end-diastolic ventricular volume do not result in increased cardiac output occurs more quickly than in adults. In addition, infants and children have relatively higher resting heart rates. As a result, increasing the heart rate can rarely increase cardiac output in children. A reduction of a child's heart rate to that of a typical adult would result in a marked decrease in cardiac output. Finally, the pediatric heart is significantly less responsive to inotropic agents because it exhibits reduced intramyocardial calcium release (Hirschl and Coran, 2003a; Rocchini, 2006).

Congenital heart defects are common, occurring in approximately one of every 120 live births. In general, these defects are classified as hypoplastic, septal, cyanotic, or obstruction defects. The septal defects are the most common, of which ventricular septal defect (VSD) is most prevalent. Most infants with septal defects have no symptoms during the first month. However, after 4 to 6 weeks of life, pulmonary resistance reaches normal levels, and thus during the second month of life congestive heart failure can occur. Hypoplasia of the heart is rare, but it is the most serious form of congenital heart disease. These defects typically result in the failure of either the right ventricle or the left ventricle to develop adequately, leaving only one side of the heart capable of pumping blood to the body and lungs. In hypoplastic left heart syndrome, the presence of a patent ductus arteriosus is critical for the infant's ability to survive until emergency surgery can be performed. Without this pathway, blood cannot circulate to the body. In hypoplastic right heart syndrome, a patent foramen ovale serves the same function. Obstruction defects occur when heart valves, arteries, or veins are abnormally narrow or blocked. Common obstruction defects include pulmonary valve stenosis, aortic valve stenosis, and coarctation of the aorta, with other types such as bicuspid aortic valve stenosis and subaortic stenosis being comparatively rare. Any narrowing or blockage can cause enlargement of the heart or hypertension. Cyanotic heart defects are named as such because they result in cyanosis. These defects include persistent truncus arteriosus, total anomalous pulmonary venous connection, tetralogy of Fallot, transposition of the great vessels, and tricuspid atresia. From a noncardiac surgery perspective, it is important to remember that many children with complex cardiac anomalies are on medications such as aspirin and sildenafil, which predispose them to bleeding.

In addition, certain types of surgically induced circulation, for example Fontan, purposely increase systemic venous pressure, which can be problematic for postoperative bleeding. Careful consideration of these variables and planning with a pediatric cardiac anesthesiologist is obligatory (Hirschl and Coran, 2003a; Rocchini, 2006).

Immunologic

Neonates have increased susceptibility to bacterial infections, which is predominantly a result of deficiencies in neonatal host defense mechanisms. Premature infants are at even higher risk. This susceptibility stems from several factors related to the immaturity of neonatal leukocytes, including neutrophils, monocytes, T and B lymphocytes, and natural killer (NK) cells, and also from deficiencies in the complement activation system.

Although the number of neutrophils is near the adult level at term (approximately 60% of circulating leukocytes), neonates have a relative inability to increase their circulating levels in response to stress or infection. This is thought to be a result of a decreased neutrophil storage pool and a result of increased margination of neutrophils. Premature infants have the added problem of having a significantly lower neutrophil count at birth. Neonatal neutrophils are also less adhesive to activated endothelium, a process that is critical to chemotaxis and migration to sites of inflammation and infection. In addition, neonatal serum is deficient in opsonins, which are necessary for neutrophil phagocytosis. Therefore, even though neonatal neutrophils are fully competent to kill bacteria, they may do so less efficiently. Unlike a decreased neutrophil storage pool, the number of monocytes in neonates is equal or greater than in adults. For unclear reasons, however, the migration of monocytes to sites of inflammation and infection is significantly delayed (Hirschl and Coran, 2003b; Upperman and Ford, 2006).

T-lymphocyte function is also impaired in neonates, despite having a significantly greater number of circulating T cells compared with adults. In addition, unlike adults, there is a greater proportion of CD4⁺ T cells than CD8⁺ T cells. The impaired function is believed to be related to their naive phenotype that is due to their lack of exposure to foreign antigens and also related to the fact that they produce relatively limited amounts of key inflammatory cytokines. B-lymphocyte function is also impaired in neonates, which is because of their inability to differentiate into IgG- or IgA-secreting plasma cells. They are able to differentiate into IgM-secreting plasma cells, but rely on maternal placental transfer for essentially all IgG. This reliance continues until the third or fourth month of life, after which time the proportion of neonatal IgG overtakes maternal IgG. Although maternal IgG is adequate for protection against most infections, strains of bacteria such as *Escherichia coli* and *Salmonella* can elicit a different immunoglobulin subtype, leaving the fetus and neonate with suboptimal immune protection. Premature infants are at even greater risk, as they are born without sufficient levels of maternal IgG (Hirschl and Coran, 2003b; Upperman and Ford, 2006).

Another lymphocytic deficiency in neonates involves the NK cells, which play an important role in protection against intracellular pathogens by targeted cell lysis. At term, the proportion of NK cells is similar to that in adult circulation, but they are functionally and phenotypically immature. For unclear reasons, their lytic potential is only 50% of adult NK cells, and it is not until late infancy that they reach their full functional potential (Hirschl and Coran, 2003b; Upperman and Ford, 2006).

The relative deficiency of immunoglobulins in neonates results in the increased reliance on the alternative, that is, antibody-independent pathway of complement activation. However, in neonates there is a reduced number of classic and alternative complement activation pathway factors. Specifically, the level of C9 is diminished, which is critical for protection against gram-negative bacteria. Breastfeeding is believed to partially compensate for these intrinsic neonatal immunologic deficiencies. Human milk contains immunoglobulins including IgG, IgM, and secretory IgA, lymphocytes, macrophages, polymorphonuclear leukocytes, and

components of the complement cascade. Because of these and other benefits, the American Academy of Pediatrics recommends continuing breastfeeding for the first 12 months of life. **Although the neonatal period presents the highest risk of infection for children, the immune system is not fully competent until approximately 8 years of age** (Hirschl and Coran, 2003b; Upperman and Ford, 2006). How the relative immunodeficiency of neonates and young children impacts surgical practice is not clear, and, as is discussed later in this chapter, evidence-based guidelines for surgical antibiotic prophylaxis in pediatric surgery are not available.

Renal

A detailed discussion of renal development can be found in Chapter 123 of this text, and therefore this section presents a very brief synopsis. Renal function begins in utero, with the first functional nephrons appearing at 8 weeks' gestation. Nephrogenesis is complete by 34 weeks. Urine production begins between 10 and 12 weeks' gestation, coinciding with the start of glomerular filtration. In utero, renovascular resistance is high, which limits renal blood flow. Immediately following birth, the distribution of renal cortical blood flow changes, with increased perfusion of the outer cortex and increased reactivity of the renal vascular bed. Consequently, the glomerular filtration rate (GFR) rises quickly despite renal blood flow remaining unchanged. In addition, water and electrolyte homeostasis is difficult to predict. GFR and tubular function double by 1 month of age (Kaskel et al, 1987), and during the first 3 months of life, renovascular resistance continues to decrease, which results in further rises in GFR. Following this relatively rapid rise, GFR continues to increase more slowly toward adult levels, which are reached by 12 to 24 months of life. The maturation of renal tubular function lags behind the maturation of glomerular function, and therefore the neonate can concentrate urine only to approximately 50% of adult capability (Greco et al, 2002; Teitelbaum and Coran, 2003a; Pierro et al, 2006).

KEY POINTS: GROWTH AND MATURATION

- Infants with a history of prematurity and/or IUGR are at risk for adverse events and account for a large proportion of neonatal deaths and long-term disability.
- Proper intrauterine growth and development are absolutely dependent on the presence of normal amniotic fluid volume, the majority of which is comprised of urine after 10 to 12 weeks' gestation.
- Lung development, in particular, depends on fluid dynamics, and processes such as oligohydramnios result in pulmonary hypoplasia.
- Neonatal and pediatric myocardium is stiffer and less compliant than in an adult, resulting in significant differences in physiologic responses and cardiovascular care.
- Many children with complex cardiac anomalies are on medications that predispose them to bleeding such as aspirin and sildenafil. In addition, certain types of surgically induced circulation, for example Fontan, purposely increase systemic venous pressure, which can be problematic for postoperative bleeding.
- Neonates have increased susceptibility to bacterial infections because of deficiencies in host defense mechanisms, and the immune system is not fully competent until 8 years of age.
- The normalization of renal function is a rapidly evolving process at birth, and adult-level GFR is not reached until 12 to 24 months of life.

PERIOPERATIVE FLUIDS

Maintenance of hydration is a fundamental and critically important concept in pediatric care. For the pediatric urologist, administration of fluids is usually for maintenance therapy in the postoperative

period or for deficit therapy in the setting of postoperative dehydration. Appropriate intraoperative fluid therapy is critical to simplify postoperative fluid management and to optimize the postoperative course. This is increasingly important given the increase in ambulatory surgery and the shorter length of hospital stays. **Perioperative fluid therapy begins with a careful and complete estimation of fluid deficit by the anesthesia team. Accurate knowledge of when exactly a patient last ate or drank is necessary to avoid the low urine output that is often observed during open bladder surgery.** If possible, urine output should be carefully monitored for the duration of surgery, and in the setting of an open lower urinary tract, the urologist should provide feedback to the anesthesiologist to ensure that the patient remains well hydrated.

Maintenance fluid replaces two losses: insensible, or evaporative, losses and urinary losses. In the perioperative period, insensible losses can vary widely with the presence or severity of several variables including fever, tachypnea, and so forth. Insensible losses represent loss of free water and generally account for one third of maintenance fluids. Urine losses are calculated as 280 to 300 mOsm/kg of water with a specific gravity of 1.008 to 1.015, but this concentration can vary depending on the patient's ability to concentrate urine. Urinary losses account for two thirds of total maintenance fluids. **The total requirements for maintenance fluids can be calculated using the Holliday-Segar formula as shown in Table 128-1 (Holliday and Segar, 1957).** After calculating the fluid requirement, children usually receive either D5 $\frac{1}{4}$ normal saline (NS) + 20 mEq/L KCl or D5 $\frac{1}{2}$ NS 20 mEq/L KCl. Children less than 6 months of age are generally given the solution with $\frac{1}{4}$ NS because of their high water needs per kilogram. Children 6 months and older, however, should receive the solution with $\frac{1}{2}$ NS (Greenbaum, 2007).

In the setting of postoperative dehydration the severity is determined as described in Table 128-2 (Siker, 2002). **Generally, deficit replacement should begin with a balanced salt solution such as lactated Ringer (LR) solution or NS to increase circulating blood volume.** Typically, a bolus of 10 to 20 mL/kg is used, but a rate of up to 40 mL/kg during the first 1 to 2 hours is well tolerated (Carvajal, 1994). The type of fluid deficit can be estimated from the

TABLE 128-1 Daily Maintenance Fluid Requirements

WEIGHT (kg)	DAILY REPLACEMENT	HOURLY REPLACEMENT
0-10	100 mL/kg/day	4 mL/kg/hr
11-20	1000 mL/day + 50 mL/kg/day	40 mL/hr + 2 mL/kg/hr
>20	1500 mL/day + 25 mL/kg/day	60 mL/hr + 1 mL/kg/hr

From Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823-32.

TABLE 128-2 Estimation of Fluid Deficit

DEFICIT	CLINICAL FINDINGS
Mild (1%-5%)	Dry mucous membranes, poor skin turgor, irritability, decreased urination
Moderate (6%-10%)	No tears, tenting of skin, lethargy, oliguria
Severe ($\geq 11\%$)	Sunken eyes and fontanelles, cold skin, anuria, tachycardia and tachypnea, hypotension, coma

Modified from Siker D. Pediatric fluids, electrolytes, and nutrition. In: Gregory GA, editor. *Pediatric anesthesia*. New York: Saunders; 2002.

patient's history, physical examination findings, electrolyte values, and serum tonicity. Types of dehydration include isotonic (serum osmolality 270 to 300 mOsm/L, serum Na⁺ concentration 130 to 150 mEq/L), hypotonic (serum osmolality <270 mOsm/L, serum Na⁺ concentration <130 mEq/L), or hypertonic (serum osmolality >310 mOsm/L, serum Na⁺ concentration of >150 mEq/L). Patients with hypertonic dehydration require careful consideration of fluid type and rate, because complications, such as cerebral edema, may occur during rehydration (Friedman, 2005; Greenbaum, 2007).

KEY POINTS: PERIOPERATIVE FLUIDS

- Maintenance of appropriate hydration is a fundamental and critically important concept in pediatric care.
- Fluid therapy must begin with an assessment of fluid deficit.
- Replacement fluids should begin with a balanced salt solution such as LR or NS.
- Maintenance fluids can be calculated using the Holliday-Segar formula.
- For maintenance fluids, children usually receive either D5 ¼ NS + 20 mEq/L KCl or D5 ½ NS 20 mEq/L KCl depending on their age and weight.

PEDIATRIC ANESTHESIA AND ANALGESIA

Psychological and Emotional Preparation

The psychological state of a child and family as well as the clinical state of each child must be thoroughly understood before anesthesia and surgical intervention can commence. If the child is not treated in an age-appropriate manner, the entire perioperative experience will likely be compromised. Conversely, if the psychological and emotional aspects of a child's condition distract caregivers from the primary medical and surgical concerns, a successful outcome might be compromised. Therefore it is imperative that the entire health care team find the ideal balance between these two considerations (Ferrari, 2008).

It is well known that significant preoperative anxiety is associated with a difficult and often prolonged anesthetic induction (Kain et al, 1996a, 1996b). Factors including the temperament and age of the child as well as the situational distress of the parent and the outcome of previous medical experiences will affect the child's anxiety level. For many children, the immediate postoperative course is a mirror of the induction experience. Children who go to sleep peacefully generally awaken in the same manner and are known to have fewer difficulties in the postanesthetic care unit (PACU). It is therefore necessary to take the time to prepare the child for the anesthetic experience in an age-appropriate manner. There is consensus among anesthesiologists regarding the need for the treatment of a child's anxiety before surgery (McCann and Kain, 2001). The development of coping skills is considered the most effective preoperative intervention, followed by modeling, play therapy, an operating room (OR) tour, and printed material (Kain et al, 1996a; O'Byrne et al, 1997; Ferrari, 2008).

The level of maturity affects a child's understanding of and response to illness (Moynihan and Kurkar, 1999). Infants fear separation from their primary caregivers and exhibit stranger anxiety; therefore it is important that parental involvement in the perioperative experience be maintained. Toddlers fear loss of control, so enabling a child to make choices, such as asking if the child has a color preference for his or her hospital gown, will diminish anxiety. Preschool-age children fear injury; they may fear, for example, that a blood draw may result in not enough blood being left in their bodies. They tend to think in concrete terms and therefore may take statements literally, so one must be cautious when choosing the language used with this age group. The school-age child typically fears that he or she may not

meet the expectations of adults. They may nod with understanding and listen intently despite not grasping what the adult is saying. They are reluctant to ask questions for fear that they should already know the answer. It is therefore imperative that expectations are clearly explained. **Adolescents fear death and usually do not understand bodily functions.** They are often panic stricken preoperatively, but try to not show any sign of this. As a result, they might remain very quiet. It is the responsibility of the care team to anticipate this anxiety and reassure the adolescent without prompting (Ferrari, 2008).

Risk of Anesthesia

Most parents will express that they experience more anxiety about the anesthetic than the risks of the surgery. Fear of anesthesia among parents originates largely from a lack of information regarding modern anesthesia practice rather than from a high probability of risk. For many families, it may be helpful to discuss specific risks of anesthesia for their child (Olsson and Hallen, 1984; Ferrari, 2008). **For a healthy child undergoing uncomplicated surgery, the risk of an adverse event is approximately 1 in 200,000 (Eichhorn, 1993).** The risk of death under anesthesia is the most feared complication. This risk is 1 in 10,000 for all patients of any age undergoing any surgical procedure (Keenan and Boyan, 1985; Tired et al, 1986; Holzman, 1994). **However, the risk of death directly attributable to the anesthetic approaches zero, although the risk of cardiac arrests resulting from anesthesia remains approximately 4.5 in 10,000 (Gobbo Braz et al, 2006).** The incidence of anesthetic-related complications and death is highest during the first year of life at 43 in 10,000, but this decreases dramatically during the second year of life to 5 in 10,000 (Tired et al, 1988). **Anesthetic risks increase by a factor of 6 during emergency procedures in all age groups (Ferrari, 2008).**

Anesthesia-Induced Neurotoxicity

The effects of anesthesia on the developing central nervous system of infants has been studied and debated for decades. In the past several years, research efforts to study this critical question have intensified, coincident with the increasing suspicion that commonly used anesthetic drugs are deleterious to the developing brain. This suspicion is based on several large epidemiologic studies and a large volume of data derived from animal studies. However, most of the epidemiologic studies are retrospective, and it is therefore impossible to eliminate the significant confounders of underlying pathology and surgery (McCann and Soriano, 2012). The Victorian Infant Collaborative Study Group reported in a retrospective study that procedures in infants, who were 27 weeks' post-conception and who underwent surgery including patent ductus arteriosus ligation, inguinal herniorrhaphy, gastrointestinal procedures, neurosurgery, and tracheostomy, were associated with blindness, cerebral palsy, deafness, and neurocognitive scores that were three standard deviations below the mean (Victorian Infant Collaborative Study Group, 1996). However, a study on premature infants with tracheoesophageal fistula repaired at birth did not have different IQ scores from their normal cohort (Bouman et al, 1999). Some prospective data are available, and one large study of infants undergoing cardiopulmonary bypass showed lower academic achievement, fine and gross motor skills, visual spatial skills, memory, sustained attention, and higher-order language skills (Bellinger et al, 2003). Despite these compelling data, definitive answers will be difficult to ascertain, as it is ethically impossible to conduct a definitive prospective randomized trial involving anesthesia in infants.

Preclinical studies in fetal and neonatal animals including chicks, mice, rats, guinea pigs, swine, sheep, and rhesus monkeys have clearly demonstrated that commonly used anesthetic, sedative, and analgesic agents are associated with neuroapoptosis and neurobehavioral deficits (Lin et al, 2014). However, the mechanisms underlying the neurotoxic effects have not been elucidated. Moreover, how the effects documented in animal species relate to

possible effects in humans is not known. Much research remains to be performed to understand these processes better and to model better the timing of human brain development.

Considering the available data, it is most likely that the most vulnerable group of patients potentially susceptible to the effects of prolonged exposure to anesthetics and sedatives during an immature state of brain development are premature infants requiring neonatal intensive care and not pediatric patients who are otherwise healthy who are undergoing brief, elective surgical procedures (Lin et al, 2014).

Basic Preoperative Preparation

A complete medical history is always the first step in a thorough preoperative assessment. The history should include the prenatal course and neonatal period because events during pregnancy and delivery may influence the child's current state of health (Means, 1997). Any previous hospital admissions should be noted. A complete review of systems is performed to evaluate for medical comorbidity that could influence the choice or outcome of anesthesia (Cote et al, 2001). The presence of cough, asthma, or a recent upper respiratory infection (URI) might predispose the child to bronchospasm, atelectasis, or pneumonia. New-onset heart murmur, cyanosis, hypertension, exercise intolerance, or a history of rheumatic fever can suggest an evolving issue that could be exacerbated by an anesthetic or with a surgical procedure. Parents should be queried for the presence of vomiting, diarrhea, malabsorption, black stools, gastroesophageal reflux, or jaundice to interrogate for electrolyte imbalance, dehydration, hypoglycemia, anemia, or the need for a rapid-sequence induction. A history of seizures, head trauma, or difficulty swallowing may indicate a metabolic derangement, increased intracranial pressure, or sensitivity to muscle relaxants. Urinary tract abnormalities may impact the state of hydration and renal function, and the urologist should clearly communicate the significance of these. Abnormal development, alterations in serum glucose levels, or a history of chronic steroid use may indicate an endocrinopathy, diabetes mellitus, hypothyroidism, or adrenal insufficiency. Lastly, a history of anemia, bruising, or excess bleeding may suggest a transfusion requirement or coagulopathy (Ferrari, 2008).

The family history should be obtained with particular attention to anesthesia-related events. Specifically, a history of liver problems in family members after anesthesia is important to elicit, as certain anesthetic agents are known rarely to cause liver damage. Malignant hyperthermia is always a concern in the pediatric population. Although most pediatric anesthesiologists refrain from routinely using succinylcholine, a family history of prolonged paralysis or mechanical ventilation after general anesthesia should be obtained. Finally, families should be asked if there is a history of unexpected death, sudden infant death syndrome, genetic defects, or familial conditions such as muscular dystrophy, cystic fibrosis, sickle cell disease, bleeding tendencies, or human immunodeficiency virus (HIV) infection (Ferrari, 2008).

Obtaining a complete medication history is essential. This includes prescription medications, nonprescription medications, and herbal or alternative therapies. Many over-the-counter cold remedies contain aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or other compounds that may interfere with coagulation. Herbal and alternative therapies are known to include significant deleterious interactions with certain prescription medications, and these must be considered before administration of anesthesia and proceeding with surgery (Cupp, 1999).

The practice of body piercing is becoming increasingly common in adolescents and young adults. Metal objects in the skin during surgery and anesthesia increase the risk of burn injury if there is an intraoperative electrocautery malfunction. In addition, metal objects can become caught on equipment in the OR, resulting in tears of the skin and subcutaneous tissue. Tongue piercing may interfere with laryngoscopy and might make securing the airway unnecessarily challenging. Therefore, patients should be counseled to remove all metal objects and disclose any body

piercing that cannot be seen during the preoperative interview (Ferrari, 2008).

The physical examination of children must begin with simple observation from a distance because the infant or child may become frightened when approached directly. A great deal can be learned about relevant physical findings without touching the child. The color of the skin including the presence of pallor, cyanosis, rash, jaundice, unusual markings, or scars from previous surgery may indicate the presence of organ system dysfunction. Because congenital anomalies often occur in association with other anomalies, abnormal facies may indicate additional anomalies. The respiratory system examination should specifically address any signs of a URI. The cardiovascular examination specifically addresses the presence of heart murmurs, which must be accurately diagnosed as innocent versus pathologic. Lesions in which bacterial endocarditis prophylaxis or protection from paradoxical air embolism are required must be documented (Ferrari, 2008).

Routine diagnostic testing in preparation for surgery is rarely indicated in healthy children, and studies that are ordered should be selected based on the general medical health of the patient and the procedure being performed. In general, measurement of hemoglobin/hematocrit in a healthy child undergoing elective surgery is unnecessary (Steward, 1991). A hemoglobin/hematocrit should be measured if significant blood loss is anticipated or if the child is younger than 6 months of age or was born prematurely. Neither the routine measurement of a coagulation profile nor a history of "easy bruising" is reliable in predicting surgical bleeding (Burk et al, 1992). A history of a previous hematoma and excessive bleeding following circumcision or large bruises should prompt an appropriate hematologic evaluation. Routine preoperative urinalysis is not indicated in children, and serum chemistries should only be performed when an abnormality is suspected. Children who are treated with anticonvulsants should have these medication levels checked, and an electrocardiogram or chest radiograph should only be ordered if the general medical condition warrants. Routine pregnancy test is controversial, and the policy of one's medical facility should be followed (Ferrari, 2008).

Nulla per Os (NPO) Guidelines

It is no longer advisable or safe to restrict children to "NPO after midnight" (Cote, 1990). This outmoded restriction increases the child's chance of undergoing induction of anesthesia when dehydrated, hypoglycemic, and cranky, all of which lead to a suboptimal situation. The risk of pulmonary aspiration of gastric contents in healthy children undergoing elective surgery is only 0.04% (Warner et al, 1999). The American Society of Anesthesiologists (ASA) has proposed practice guidelines that may be followed when determining NPO restrictions in children (American Society of Anesthesiologists, 1999). **The ASA recommends fasting from clear fluids for 2 hours before anesthesia.** Clear liquids consist of water, nonparticulate juices (e.g., apple, white grape), Pedialyte, and Popsicles. **Fasting from breast milk for 4 hours and formula for 6 hours is recommended.** **The suggested fasting period for solid food is 6 hours for regular meals and 8 hours for fat-containing meals.** However, a large survey of pediatric institutions recommends fasting from all solids for at least 8 hours in all children (Ferrari et al, 1999). However, individual institutions may have specific practice guidelines that differ from those mentioned here.

Immunizations

The timing of vaccinations in the perioperative period has been a controversial topic. It is known that both anesthesia and surgery exert immunomodulatory effects, and some believe that these effects may exert additive or synergistic influences on vaccine efficacy and safety (Siebert et al, 2007). This risk, however, is theoretical and there are no guidelines that address the issue. Based on an exhaustive review of the literature, Siebert et al concluded that the immunomodulatory influence of anesthesia during elective

surgery is both minor and transient, lasting around 48 hours, and that the current evidence does not provide any contraindication to the immunization of healthy children scheduled for elective surgery. However, respecting a minimal delay of 2 days (inactivated vaccines) or 14 to 21 days (live attenuated viral vaccines) between immunization and anesthesia may be useful to avoid the risk of misinterpretation of vaccine-driven adverse events as postoperative complications (Siebert et al, 2007).

Special Circumstances

The Child with an Upper Respiratory Infection

Whether to proceed with an elective operation in a child with an active URI is one of the most difficult and fundamental questions in pediatric anesthesia (Hinkle, 1989). Children typically experience three to nine URI episodes per year, and the majority occur during the winter months (Van der Walt, 1995). The classic signs and symptoms include fever, irritability, restlessness, sneezing, nasal discharge, nasal obstruction, headache, malaise, and anorexia (Tait and Malviya, 2005). Children between the ages of 3 months and 3 years also experience fever early in the course of the illness, and in general younger children develop more severe infections than older children. It is likely that during the winter months a child has a cold, is just recovering from a cold, or is about to catch a new cold (Ferrari, 2008).

A cough is a sign of lower respiratory involvement and should be evaluated for origin (upper airway or bronchial) and quality (wet or dry). Most children will have clear breath sounds when auscultated during quiet respirations. It is during coughing and crying that rales and rhonchi will be best detected (Ferrari, 2008).

Definitive criteria for canceling surgery have not been established, and the decision is often subjective. Criteria that suggest that cancellation should be considered include the necessity for endotracheal intubation, parental observation that the child is acutely ill on the day of surgery, the presence of nasal congestion and cough, a history of secondary smoke exposure, and active sputum production (Cohen and Cameron, 1991; Parnis et al, 2001). Decisions to cancel surgery should be made in conjunction with the surgeon and based on the type of procedure, the urgency of the procedure, and the child's overall medical condition. Most authors agree that surgery may be scheduled after the acute symptoms have resolved and no sooner than 3 to 4 weeks after the initial evaluation (Ferrari, 2008). A suggested algorithm is provided in Figure 128-1 (Tait and Malviya, 2005; Zuckerberg and Maxwell, 2009).

Asthma

Asthma is one of the most common chronic pediatric illnesses and is characterized by bronchoconstriction, hypersecretion of mucus, mucosal edema, and desquamation of inflammatory cells. The

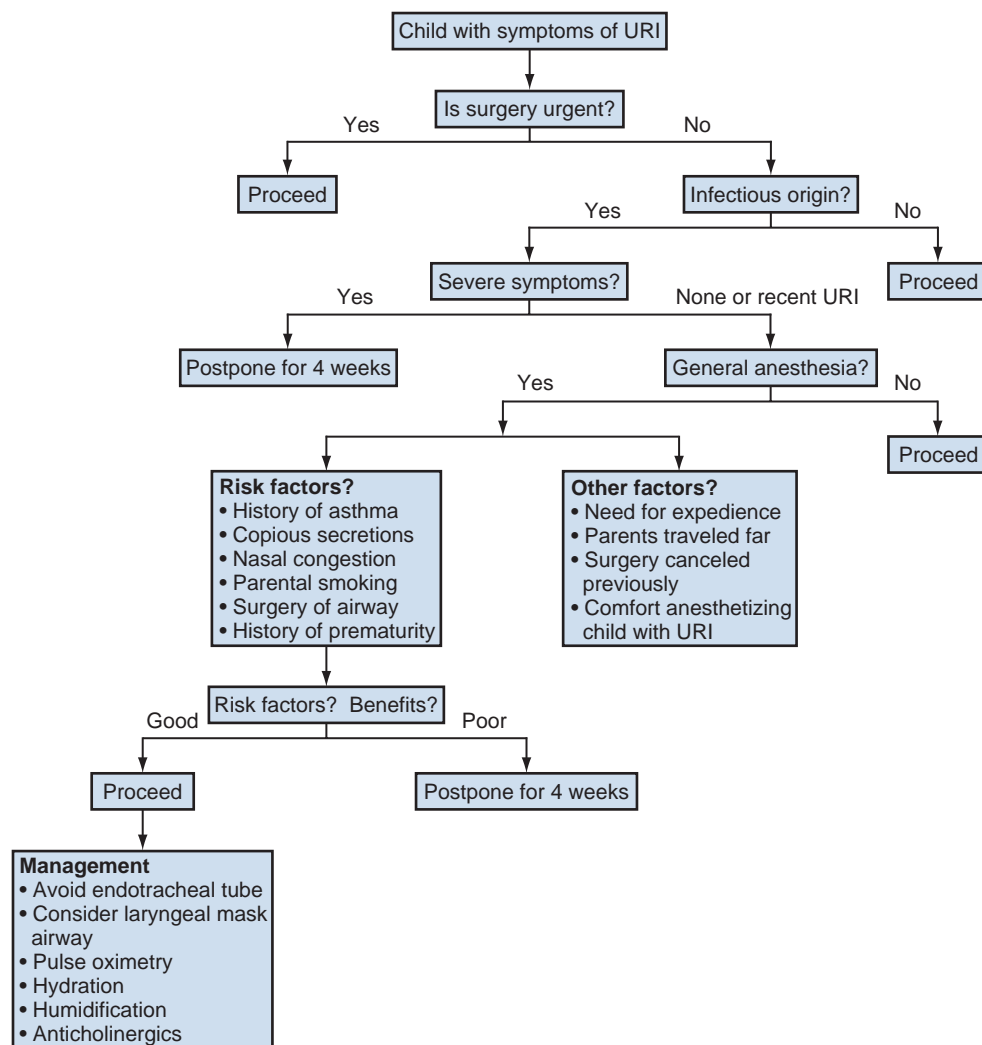

Figure 128-1. Preoperative decision making in children with upper respiratory infection (URI) symptoms. (From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory infection: still a dilemma? *Anesth Analg* 2005;100:59–65.)

hyperactive airways are sensitive to stimulation, and endotracheal intubation is one of the most noxious. In preparing children with asthma for surgery, it is important to note whether a child is on maximal medical therapy and whether wheezing persists despite this. All asthma medications, both inhaled and oral, should be administered up to and including the morning of surgery. If children are not on maintenance therapy and only require treatment during acute exacerbations, this therapy should be administered for the 48 hours before anesthesia even if the child is asymptomatic. If performed, recent pulmonary function test (PFT) results should be available, and children as young as 5 years can cooperate with PFT (Ferrari, 2008).

The Former Premature Infant

Advances in neonatology have resulted in an increasing number of premature infants surviving. These infants generally have complex medical issues and often require surgery for a variety of reasons. Urgent urologic surgery in these babies, however, is rare. From a perioperative perspective, the major issue for these infants is the risk of apnea associated with bradycardia. Apnea is usually central and is the result of brainstem immaturity, which predisposes these infants to more significant apnea during the postoperative period (Kurth et al, 1987). This risk is less than 1% in a 35-week-old former premature infant if surgery is delayed until after 54 weeks' postconceptual age (Cote et al, 1995). If surgery cannot wait, then postanesthetic apnea monitoring is required for 24 hours. Postanesthetic apnea has also been reported in full-term infants younger than 4 weeks of age, and therefore similar monitoring is required (Noseworthy et al, 1989). In addition, a hematocrit less than 30 is associated with an increased risk of postanesthetic apnea in the former preterm infant, and therefore a preoperative hematocrit is warranted in all premature infants undergoing surgery (Welborn et al, 1991; Ferrari, 2008).

Spina Bifida

Spina bifida is one of the most common birth defects, and urologists should be involved in the care of these patients beginning immediately after birth. The average incidence of spina bifida in the United States is 0.7 per 1000 live births. The incidence is higher on the east coast of the United States than on the west coast, and it is higher in whites (1 case per 1000 live births) than in blacks (0.1 to 0.4 case per 1000 live births) (Lemire, 1988). These children are frequent visitors to the OR and require careful preoperative preparation because of their frequent comorbidities. There is a high incidence of sensitivity to latex-containing products, so all patients with spina bifida should be regarded as having a latex allergy. A significant number of children with spina bifida have ventriculo-peritoneal (VP) shunts to manage the hydrocephalus. At Children's Hospital Boston we have a mandatory protocol for elective surgery preparation in children with VP shunts to ensure that they are functional before the administration of anesthesia (Fig. 128-2).

Children with Cancer

Children with a current or previous malignancy should have all chemotherapy documented. Anthracyclines (doxorubicin [Adriamycin]) can cause myocardial dysfunction, and others such as mitomycin C and bleomycin can cause pulmonary dysfunction. Children who have been treated with anthracycline agents require echocardiography if the cumulative dose is greater than 150 mg/m² (Lipshultz et al, 1991). Any child with a history of congestive heart failure who has not had a postanthracycline echocardiogram or an echocardiogram within 2 years before the time of anesthesia requires a preoperative echocardiogram (Ferrari, 2008).

The Child of a Jehovah's Witness

Jehovah's Witnesses refuse blood transfusions because of the belief that the "life force" resides in their blood. Although adult Jehovah's

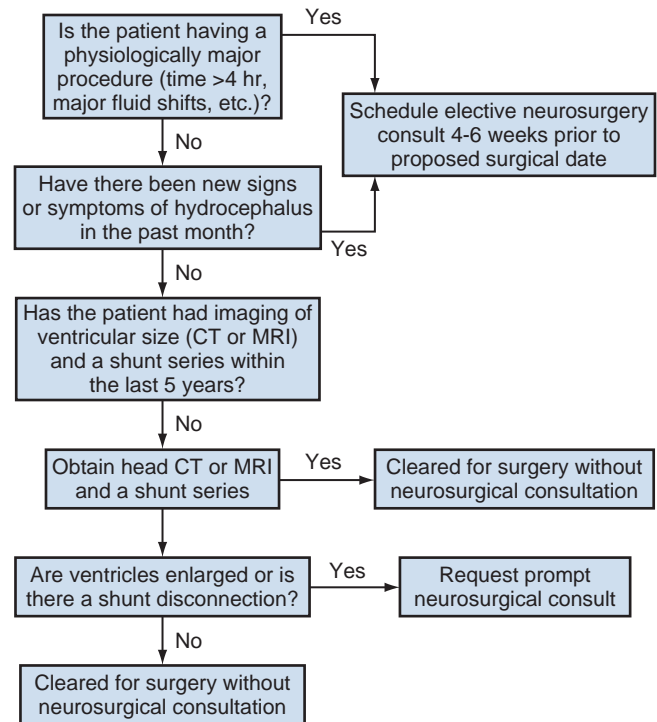

Figure 128-2. Preoperative assessment of patients with shunted hydrocephalus. CT, computed tomography; MRI, magnetic resonance imaging. (From Children's Hospital Boston, © 2008.)

Witness patients may choose to refuse lifesaving blood transfusions, pediatric patients, as minors, do not have that same right. It is therefore imperative that the surgical and anesthesia teams define a plan with the parents in the event that blood is required. Perioperative volume expanders such as albumin, hemodilution, and blood banking are acceptable to some individuals, depending on their interpretation of biblical passages (Benson, 1989). Most medical care providers agree that in an emergency it is unacceptable for a parent to make a conscious decision that could result in the loss of a minor child's life; in such cases, appropriate medical therapy, including transfusion of blood products, is administered against the wishes of the family (Swartz, 1985). In most circumstances, the courts have intervened to allow blood transfusions over the religious objections of the parents. No child of Jehovah's Witness parents should die for lack of transfused blood without a physician seeking a court order to provide blood (Waisel et al, 2001). Consultation with a pediatric hematologist may be helpful to optimize the preoperative preparation, which may include oral iron therapy 2 to 3 weeks before surgery.

Congenital Adrenal Hyperplasia

Pediatric urologists frequently treat patients with congenital adrenal hyperplasia (CAH), and the patients' condition requires careful perioperative preparation. The most common form of CAH is 21-hydroxylase deficiency, which results in an excess of progesterone and 17-hydroxyprogesterone. These hormones are then peripherally converted to androgens, which result in the virilization of affected girls. Approximately 75% of these patients are also salt-wasters because of impaired mineralocorticoid production. In addition, adrenal catecholamine production is deficient in patients with CAH. The cornerstone of the medical management of CAH is life-long hormonal replacement. Children are given hydrocortisone, and salt-wasting patients also require fludrocortisone and sodium chloride supplementation. Perioperatively, it is critical to clearly understand the nature of the child's CAH and how well and stably it is medically managed. Baseline parameters including

hydration status, blood pressure, and electrolytes are determined. The usual doses of hydrocortisone are inadequate to cover the physiologic stress of surgery, and thus CAH patients are typically administered 100 mg/m² hydrocortisone in 4 divided intravenous doses for the first 24 hours and then slowly tapered (Zuckerberg and Maxwell, 2009). A clear perioperative plan for hormonal supplementation should be developed in conjunction with the child's endocrinologist.

Regional Anesthesia

There has been increased interest in regional anesthesia in children mainly as a result of two general factors: decreased general anesthetic requirement and improved postoperative pain management. At Children's Hospital Boston, we routinely use two related types of regional anesthesia: single-shot caudal blocks and epidurals. Caudal blocks are typically used in patients undergoing bilateral groin surgery, those undergoing open ureteroneocystostomy, and in neonatal patients in whom we would like to limit the administration of narcotics. Epidural anesthesia is generally used in children undergoing renal surgery or extensive pelvic surgery.

Single-shot caudal blocks are one-time injections of local anesthetic agents into the epidural space, and these can provide analgesia in the T10 to S5 dermatome region. The most common local anesthetic used is bupivacaine 0.125% to 0.25% with epinephrine administered in volumes of 0.5 to 2 mL/kg (not to exceed toxic doses measured in mg/kg) (Kraemer and Rose, 2009). The addition of clonidine, 1 to 2 µg/kg to a maximum of 30 µg, may enhance the duration and intensity of the caudal block (Constant et al, 1998). In addition to the one-time injection, an angiocatheter may be left in place in the caudal region for additional postoperative local anesthetic administration. One of the most frequent complications with caudal blocks is the inadvertent needle placement into the vasculature, the intrathecal space, or even the bone in very young children; however, this rate is low (0.7 per 1000) (Kraemer and Rose, 2009).

Continuous epidural analgesia (CEA) provides excellent perioperative analgesia in infants and children undergoing thoracic, abdominal, pelvic, and perineal surgery. The epidural space may be accessed at any level, but it is most frequently approached at the lumbar or caudal region in children. If the epidural needle touches the spinal cord, the awake patient will react and spinal cord injury can thereby be avoided. However, the vast majority of epidural catheters in children are placed under general anesthesia because it is generally considered safer to place epidurals in children who are

not moving. The risk of neurologic injury with lumbar epidural catheter placement is exceedingly low, but thoracic placement does carry a higher risk of spinal cord injury should the needle be advanced too far. As such, direct thoracic placement under general anesthesia should be performed only by very experienced personnel and with careful consideration of the potential risks and benefits (Greco et al, 2002). In selected cases, catheters can be advanced to the thoracic level from a lumbar or caudal route under fluoroscopic guidance. The location of the catheter tip can be confirmed with a contrast epidurogram (Greco et al, 2002). Epidural drug selection is individualized and varies with site of surgery, location of the epidural, and patient-specific factors. In general, local anesthetics are infused in combination with opioids, clonidine, or both. Clonidine is used because of the same benefits as discussed for single-shot caudal blocks, and clonidine is used preferentially over opioids if possible, because it does not cause adverse effects typical of opioids including pruritus, nausea, ileus, urinary retention, or respiratory depression (Greco et al, 2002; Hirschl and Coran, 2003c). The risk of local anesthetic toxicity is one of the main concerns that require continuous monitoring during CEA. Hospitals should have a dedicated team of anesthesiologists and nurses immediately available to manage any emergent problems with pain control or adverse effects with CEA. The epidural site should be evaluated daily for signs of infection. Protocols and CEA order sets should include patient monitoring parameters and neurologic assessment every 4 hours (Kraemer and Rose, 2009).

Postoperative Pain Management

It is incumbent on pediatric care providers to make every attempt possible to assess their patients' pain, which may be challenging given the limited cognition and language skills of infants and children. Pain assessment tools are well established and widely available, but assessing pain in neonates, infants, and nonverbal or developmentally delayed children is still limited (Kraemer and Rose, 2009). In general, the younger the child, the less likely he or she can clearly delineate between levels of pain using pain scales. In general, however, children 8 years of age and older can reliably report pain on the visual analog scale used in adults. Children between the ages of 3 and 7 years can better report pain using a "faces" scale that presents a series of drawings depicting increasing levels of distress (Kraemer and Rose, 2009). Table 128-3 provides examples of some routinely used pediatric pain scales. In addition to the child, parents are often an excellent source of information regarding their child's pain.

TABLE 128-3 Pediatric Pain Scales

SCALE	TYPE	AGES	SCORING INDICATORS
PIPP	Behavioral and physiologic parameters Procedural pain	Term and preterm infants	Gestational age Behavioral state Heart rate, SpO ₂ Facial expression
CRIES	Behavioral and physiologic parameters Postoperative pain	32-60 wk	Crying, increased O ₂ Increased vital signs Expression Sleeplessness
FLACC	Behavioral parameters	<3 yr or unable to self-report	Face, legs, activity, cry, consolability
Faces	Self-report	3-12 yr	Happy face to saddest face yield numeric 0-10 score
VAS	Self-report	>7 yr	0 = no pain 10 = maximum pain

CRIES, crying, increased O₂, increased vital signs, facial expression, sleeplessness; FLACC, face, legs, activity, cry, consolability; PIPP, premature infant pain profile; VAS, visual analog scale.

TABLE 128-4 Acetaminophen Dosing

ROUTE OF ADMINISTRATION	PRETERM INFANTS (28-32 wk)	PRETERM INFANTS (>32 wk)	FULL-TERM INFANTS AND CHILDREN <50 kg	CHILDREN >50 kg, ADOLESCENTS, AND ADULTS
Oral	12.5 mg/kg q6h PRN for 72 hr	12.5 mg/kg q4h PRN for 72 hr	12.5 mg/kg q4h PRN for 72 hr	325-975 q4h PRN for 72 hr
Rectal	20 mg/kg q12h PRN for 72 hr	15 mg/kg q8h PRN for 72 hr	15-20 mg/kg q4h PRN for 72 hr	325-975 q4h PRN for 72 hr
Intravenous	Not approved <2 yr old	Not approved <2 yr old	≥2 yr old: 15 mg/kg q6h or 12.5 mg/kg q4h	1000 mg q6h or 650 mg q4h
Maximum dose	50 mg/kg/day	90 mg/kg/day	Oral/rectal: 90 mg/kg/day (≤4 g/day) IV: 75 mg/kg/day (≤3750 mg/day)	4 g/day

Based on Boston Children's Hospital formulary.

Based on severity, pediatric pain management involves targeting several of the complex elements of pain transduction, transmission, modulation, and perception (Kraemer and Rose, 2009). Common multimodal plans include NSAIDs acting on the periphery, regional block of peripheral nerves, nerve roots, or spinal cord, and/or opiates acting centrally. A balanced approach such as this can minimize the adverse effects of each and can work synergistically to manage acute pain best.

For children who undergo nonambulatory surgery and who do not have CEA, patient-controlled analgesia (PCA) is an excellent option for treating moderate to severe pain. **Children as young as 5 years old have successfully used PCA with proper education and guidance, but PCA is routinely used in children aged 7 and older (McDonald and Cooper, 2001).** The use of PCA mandates institutional/departmental monitoring requirements that include respiratory rate, pulse oximetry, heart rate, blood pressure, pain assessment, and level of consciousness. When used with appropriate monitoring, PCA is safe, effective, and highly reliable. In younger children or those unable to control their PCA reliably, nurse- or parent-controlled analgesia can be used with similar success and efficacy.

Oral pain medications include nonopioid and opioid analgesics. Nonopioid options include acetaminophen and NSAIDs. **Acetaminophen is the most widely used antipyretic and analgesic medication in pediatrics, and it is commonly combined with opioids for patients with moderate to severe pain.** When dosed appropriately, acetaminophen can be used safely in neonates. It is normally metabolized in the liver primarily by glucuronidation and sulfation. Neonates and infants primarily conjugate by sulfation, and the mature ratio of glucuronidation/sulfation is reached at approximately 12 years of age. **The concerning feature of acetaminophen is that overdose can lead to liver necrosis and failure.** This is because in supranormal doses acetaminophen is metabolized by the oxidative cytochrome P450 pathway, which results in a highly hepatotoxic metabolite. Acetaminophen is available in several formulations including drops (80 mg/0.8 mL), elixir (160 mg/5 mL), chewable tablets (80 mg and 160 mg), dissolvable tablets (160 mg), tablets (325 mg and 500 mg), suppositories (80 mg, 120 mg, 325 mg, and 650 mg), and intravenous solution. The suggested dosing of acetaminophen is provided in Table 128-4.

NSAIDs are commonly used for postoperative pain because they provide excellent analgesia and are well tolerated. A review of short-term ibuprofen use in a large cohort of children showed no increase in renal or gastrointestinal adverse effects compared with acetaminophen (Lesko and Mitchell, 1995). NSAIDs are more similar than they are different. Adult clinical trials, outcome studies, and systematic reviews indicate that there is no NSAID that possesses uniquely greater analgesic effect than others and that the oral, rectal, and parenteral routes of administration are equally effective (Greco et al, 2002). Like acetaminophen, ibuprofen is available in several preparations including drops (50 mg/1.25 mL), elixir

TABLE 128-5 Opioid Dosing

OPIOID	ROUTE/AGE GROUP	DOSE/INTERVAL
Morphine	Intravenous bolus:	
	Full-term neonate	10-25 µg/kg q2-4h
	Preterm neonate	25-50 µg/kg q3-4h
	Infants and children	50-100 µg/kg q3-4h
	IV infusion:	
	Preterm neonate	2-5 µg/kg/hr
	Full-term neonate	5-10 µg/kg/hr
	Infants and children	15-30 µg/kg/hr
Codeine	Oral	0.5-1 mg/kg q4h
Oxycodone	Oral	0.05-0.15 mg/kg q4h

Modified from Kraemer FW, Rose JB. Pharmacologic management of acute pediatric pain. *Anesthesiol Clin* 2009;27:241-68.

(100 mg/5 mL), chewable tablets (50 mg and 100 mg), and tablets (200 mg, 400 mg, 600 mg, and 800 mg). Intravenous ibuprofen is available in the United States, but has not been approved for use in pediatric patients for the treatment of pain. Ibuprofen should be used routinely in children aged 6 months and older. For analgesia, a single dose of 15 mg/kg can be used. However, if repeated doses are anticipated or planned, dosing should be 4 to 10 mg/kg/dose every 6 to 8 hours, with a maximum daily dose of 40 mg/kg/day.

Ketorolac is the only parenteral NSAID (15 mg/mL and 30 mg/mL) available for use in the United States to treat pediatric pain, and it has been used as an adjuvant to opioids and a single agent for the treatment of postoperative pain. We routinely use ketorolac in children at least 6 months of age, but it is approved for use in children 2 years or older. **We have found that in addition to excellent analgesia, ketorolac significantly reduces the incidence and severity of bladder spasms (Park et al, 2000), and we routinely use ketorolac following bladder surgery.** However, significant adverse effects have been reported including acute renal failure, prolongation of bleeding times, and hypersensitivity reactions, and therefore caution is warranted (Kraemer and Rose, 2009). Because of this, we do not use ketorolac in patients with renal insufficiency, renal scarring, a solitary kidney, NSAID sensitivity, or in a patient in whom a risk of significant postoperative bleeding is feared. Dosing of ketorolac is 0.25 to 0.5 mg/kg every 6 hours with no loading dose requirement.

Opioids are commonly used for moderate to severe pain, and for the vast majority of children they provide excellent analgesia with a wide margin of safety. They affect analgesia by central nervous system neuronal inhibition. The commonly used opioids in the pediatric population are µ₁ agonists and include morphine, hydromorphone, methadone, fentanyl, codeine, oxycodone, and hydrocodone (Table 128-5). Opioids can be administered through

several routes, including orally, intravenously, intramuscularly, subcutaneously, rectally, transdermally, or transmucosally. Oral administration is usually the easiest route and provides relatively constant drug plasma levels. **Despite their general efficacy, there is substantial individual variation in opioid dose requirements. The adequate opioid dose is that which provides pain relief but does not result in excessive somnolence or respiratory depression.** Morphine is the standard opioid to which all others are compared (Greco et al, 2002; Kraemer and Rose, 2009). It is metabolized in the liver, the elimination half-life is longer, and the clearance is decreased in newborns. This difference is even more substantial in preterm neonates. Within 2 months of age, however, the elimination half-life and clearance reach adult levels. There is no established optimal morphine plasma concentration, and therefore the appropriate dose needs to be established for each patient while being carefully monitored for respiratory depression.

Codeine is available in elixir form and is the most common orally administered opioid in young children. It is often combined with acetaminophen (acetaminophen 120 mg with codeine 12 mg/5 mL), and in this form it is more effective. Dosing of codeine is 0.5 to 1 mg/kg every 4 hours, but the dose of acetaminophen needs to be carefully considered to avoid acetaminophen toxicity. The maximum dose based on acetaminophen content for children weighing less than 45 kg is acetaminophen 90 mg/kg/day and for children weighing more than 45 kg it is acetaminophen 4 g/day. **Codeine itself is a relatively weak opioid given its extremely low affinity for opioid receptors, and most of its analgesic effect is a result of the 10% that is metabolized to morphine.** The metabolism to morphine is predominantly via O-demethylation by the cytochrome P450 enzyme CYP2D6, which is known to show genetic polymorphism (Williams et al, 2001). **Therefore, variations in CYP2D6 will result in variable abilities to metabolize codeine.** In this way, individuals may be classified as poor metabolizers or ultrarapid metabolizers, depending on the phenotype of their CYP2D6 enzyme. A total of 3% of Caucasians and 40% of people of North African descent are ultrarapid metabolizers, resulting in dangerously high plasma levels of morphine (Gasche et al, 2004). Conversely, 7% to 10% of Caucasians are poor metabolizers of codeine, and receive little or no analgesia from codeine administration (Kraemer and Rose, 2009). The disastrous consequences of CYP2D6 variability is highlighted by the report of the death of a 2-year-old child who was given codeine at home following a routine tonsillectomy (Ciszkowski et al, 2009). Genotyping of the patient showed duplication of the CYP2D6 allele (ultrarapid metabolizer), and the plasma concentration of morphine was 32 ng/mL (>20 ng/mL results in respiratory depression). **Because of this risk, we use oxycodone exclusively, which appears to have less variable metabolism.**

Oxycodone is available in tablet and liquid form, and it is also commonly combined with acetaminophen. The combined preparation is commonly used in children, and it is available in solution (oxycodone 5 mg and acetaminophen 325 mg/5 mL) and in tablet form (oxycodone 2.5 to 10 mg and acetaminophen 300 to 650 mg). The initial dose is based on the oxycodone content, but the maximum daily dose is based on the acetaminophen content. Based on pain severity, the initial oxycodone dose is 0.05 to 0.3 mg/kg/dose. The maximum dose based on acetaminophen content for children weighing less than 45 kg is acetaminophen 90 mg/kg/day, and for children weighing more than 45 kg it is acetaminophen 4 g/day. A strategy that we commonly use for most outpatient surgical procedures is a scheduled regimen of alternating acetaminophen and ibuprofen every 3 hours for the first 48 hours after surgery. Plain oxycodone can then be used in addition if the acetaminophen and ibuprofen prove inadequate. This approach is commonly used in pediatrics for fever reduction and has been shown to be safe in the surgical setting (Bauer et al, 2010; Wong et al, 2013). Although we use plain oxycodone exclusively, its widespread availability appears to be limited, as many community pharmacies consider it a specialty item and do not keep it in regular stock. If this is the case, then a combined acetaminophen/oxycodone preparation is favored,

which will complicate the alternating scheme of acetaminophen and ibuprofen.

KEY POINTS: PEDIATRIC ANESTHESIA AND ANALGESIA

- Surgical preparation is a multifaceted endeavor that involves the consideration of the medical and psychological needs of children and their families, all of which vary with the child's age and developmental status.
- The risks associated with anesthesia in a healthy child undergoing uncomplicated surgery are extremely low. In addition, it is currently unknown whether anesthesia is neurotoxic to the developing brain.
- Routine diagnostic testing for surgery is rarely indicated in healthy children and studies that are ordered should be selected based on the general health of the patient and the procedure being performed.
- Children should not be kept "NPO after midnight"; the ASA has provided guidelines to optimize patient hydration and to minimize risk.
- URI is very common in childhood; elective surgery should be scheduled after the acute symptoms have resolved and no sooner than 3 to 4 weeks after the initial evaluation.
- Children with VP shunts should undergo evaluation to ensure proper shunt function before undergoing major surgery.
- Regional anesthesia plays an important role in several urologic surgeries, and the most commonly performed are the single-shot caudal block and continuous epidurals.
- Based on severity, pediatric pain management involves targeting several of the complex elements of pain transduction, transmission, modulation, and perception.
- Acetaminophen is the most widely used analgesic in pediatrics; ibuprofen is also commonly used and children are unlikely to experience adverse renal or gastrointestinal effects.
- Opioids are used for moderate to severe pain and there is substantial variation in individual opioid dose requirements.
- Codeine has highly variable efficacy because of genetic polymorphism of the CYP2D6 liver enzyme; patients may be poor metabolizers resulting in little or no analgesia or they might be rapid metabolizers resulting in dangerous levels of postmetabolism opioid plasma levels.

SURGICAL PREPARATION AND INTRAOPERATIVE CONSIDERATIONS

Surgical Preparation

Antimicrobial Prophylaxis

Because there are no available guidelines from any of the pediatric urologic or surgical societies, whether to use prophylactic antibiotics in children undergoing surgery remains an individual and non-evidence-based decision. This decision is generally not controversial for major surgery for which surgical antimicrobial prophylaxis (SAP) is routinely administered, but it is so for minor procedures such as orchidopexy, herniorrhaphy, and circumcision. The Centers for Disease Control and Prevention (CDC) provided guidelines for SAP (Mangram et al, 1999), but these were broad and general and did not specifically address urologic surgery. In 2001 the European Association of Urology published urology-specific guidelines, but pediatric procedures were not specifically addressed. The Japanese Urological Association published comprehensive SAP guidelines that included pediatric procedures (Matsumoto et al, 2007), but these were not evidence-based and were formulated based on the opinions and practice patterns of academic pediatric urologists. The

CDC surgical wound classification system of clean (class I), clean-contaminated (class II), contaminated (class III), and dirty/infected (class IV) can be applied to pediatric urologic procedures, and examples are provided in Table 128-6. In general, SAP is recommended for: (1) all surgery in neonates younger than 72 hours of age because of possible exposure to maternal pathogens and

particularly compromised immunologic capacity, (2) major class II surgery, and (3) all class III and class IV surgical procedures (2004). Antibiotic use in class I and minor class II operations is not studied, and this use remains based on individual surgeons' preferences. Recommendations for SAP are provided in Table 128-7. The timing of SAP administration is critically important, and the first dose should be administered from 30 minutes to 3 hours before incision to achieve bactericidal levels of the antibiotic at the site of incision.

TABLE 128-6 Wound Classification in Pediatric Urologic Surgery

WOUND CLASSIFICATION	PROCEDURES
Clean	Nephrectomy, adrenalectomy, retroperitoneal tumor resection, orchidopexy, herniorrhaphy
Clean-contaminated	Nephroureterectomy, partial nephrectomy, pyeloplasty, ureteral reimplant, other intravesical procedures, exstrophy closure, partial cystectomy, hypospadias repair, other genital surgery, cystoscopy, transurethral incision of ureterocele, transurethral ablation of posterior urethral valves
Contaminated	Bladder enterocystoplasty, continent urinary diversion
Dirty	Open trauma of the urinary tract, operations for infected kidney, ruptured bladder augmentation

Modified from Yamamoto S, Shima H, Matsumoto T. Controversies in perioperative management and antimicrobial prophylaxis in urologic surgery. *Int J Urol* 2008;15:467–71.

Thromboembolism Prophylaxis

Venous thromboembolic events (VTEs) in children are rare when compared with adults. The incidence of VTEs in children is estimated to be between 0.07 and 0.14 per 10,000 in the general population and 5.3 per 10,000 for pediatric hospital admissions (Andrew et al, 1994; van Ommen et al, 2001). In general, the frequency of VTEs in children is one tenth that of adults (Levy et al, 2004), and several factors are believed to contribute to this difference. These include lower levels of thrombin in childhood, enhanced levels of thrombin inhibitors in children, and significantly lower levels of various clotting factors at different times in childhood (Jackson and Morgan, 2008). Despite the rare incidence, it is believed to be increasing, most likely owing to increased awareness and diagnosis and improved life expectancy of children with serious prothrombotic diseases such as congenital heart disease, cancer, and extreme prematurity (Jackson and Morgan, 2008). The incidence of VTE in the pediatric population is bimodal, occurring most often in infants aged less than 1 year and in adolescents. These two age groups account for more than 70% of VTEs. Risk factors in infants include diminutive blood vessels, a unique hemostatic system, and the use of central venous catheters (CVCs). Risk factors in adolescents include smoking, contraception, and obesity (Sandoval et al, 2008). In general, the greatest risk factor is the presence of a CVC. There are no clear guidelines in pediatric surgery for the use of thromboprophylaxis, and individual institutions typically develop local policy. In general, for pediatric noncancer urologic surgery we use thromboprophylaxis for all peri- and postpubertal patients,

TABLE 128-7 Recommendations for Surgical Antimicrobial Prophylaxis

OPERATION	LIKELY PATHOGENS	PROPHYLACTIC ANTIBIOTICS	PREOPERATIVE DOSE
Neonatal (<72 hr old) surgery	Group B streptococci, enteric gram-negative bacilli, enterococci	Ampicillin + gentamicin	50 mg/kg ampicillin 2.5–3 mg/kg gentamicin
Class I (clean)	<i>Staphylococcus epidermidis</i> , <i>Staphylococcus aureus</i> , streptococci, gram-negative enteric bacilli	Cefazolin or Vancomycin (if MRSA or MRSE likely)	25 mg/kg 10 mg/kg
Class II (clean-contaminated)	Enteric gram-negative bacilli, enterococci	Cefazolin or Ampicillin + gentamicin	25 mg/kg 50 mg/kg ampicillin 2.5–3 mg/kg gentamicin
Class III (contaminated)	Gram-negative enteric bacilli, enterococci, anaerobes	Cefoxitin or Cefotetan	40 mg/kg 40 mg/kg
Class IV (dirty/infected)	Gram-negative enteric bacilli, enterococci, anaerobes	Cefoxitin or Cefotetan ± gentamicin or Gentamicin + clindamycin	40 mg/kg 40 mg/kg (±2 mg/kg gentamicin) 2 mg/kg gentamicin + 10 mg/kg clindamycin

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.

Modified from McInerney TK, Adam HM, Campbell DE, et al, editors. American Academy of Pediatrics textbook of pediatric care. Elk Grove Village (IL): American Academy of Pediatrics; 2009.

because it is assumed that the adult risk of VTE develops after sexual maturation. The extent of thromboprophylaxis, which can include compression stocking and/or sequential compression devices plus or minus subcutaneous enoxaparin, is made on a case-by-case basis based on the assessment of an individual child's risk factors.

Hair Removal

Peripubertal children and postpubertal adolescents may have a significant amount of hair at the sites of urologic procedures. The questions of appropriate timing and method of hair removal have been debated because they are thought to impact significantly the development of surgical site infections (SSIs). Data indicate that there is a higher risk of SSI when hair is removed on the day of or night before surgery and also with the use of razors. Lower rates of SSI are achieved by using clippers or depilatory agents immediately before surgery (Tanner et al, 2007). Based on this, our policy is to remove hair at the time of immediate presurgical preparation in the OR using clippers. Razors are no longer available in our ORs.

Intraoperative Considerations

Blood Loss and Transfusion Requirement

Blood volume in children varies with age, but estimates can be between 75 and 80 mL/kg (Linderkamp et al, 1977). In general, transfusion of packed red blood cells (PRBCs) is indicated for a hematocrit of less than 24% with signs and symptoms of anemia in the perioperative period or blood loss of more than 15% of the blood volume (Roseff et al, 2002). In cases of blood loss less than 15% of the blood volume, volume replacement with crystalloid is usually adequate. Massive bleeding involving the loss and replacement of 1 blood volume within 24 hours can lead to serious complications, and the mortality rate associated with this situation is approximately 40% (Radel, 2009). In an extreme situation, non-crossmatched O Rh-negative blood may be used, but all efforts should be made to use blood-type-specific blood products. In general, platelet transfusion is reserved for a platelet count of less than 50,000/mL. Fresh-frozen plasma is used if the prothrombin time or partial thromboplastin time is more than 1.5 times normal (Radel, 2009). In our experience, the pediatric urologic surgical case most likely to require transfusion of PRBCs has been newborn complete primary repair of bladder exstrophy, with 75% of boys and 29% of girls requiring intraoperative transfusion (Borer et al, 2005).

The risks associated with transfusion are minimal, but they are a consistent source of worry for parents. The elimination of paid donors, more thorough donor screening, and increasingly sophisticated donor blood testing have led to a significant decrease in the incidence of infection transmitted by transfusion (Zuckerberg and Maxwell, 2009). The incidence of transfusion-associated hepatitis B is 1 in 63,000, and the risk of transfusion-transmitted hepatitis C is 1 in 103,000 (Schreiber et al, 1996). The risk of transfusion-transmitted HIV is estimated to be between 1 in 450,000 and 1 in 600,000 (Schreiber et al, 1996). In addition to the risk of transmission of infection, transfusion reactions occur in 2% to 3% of cases. Of these, 41% are febrile and nonhemolytic, 58% are urticarial, and 1% are delayed hemolytic (American Medical Association, 1985).

Thermoregulation

Infants and children are more susceptible than adults to changes in ambient temperature because they have a relatively large body surface to mass ratio, less insulating tissue such as fat or hair, and limited energy reserves. Neonates are especially sensitive to cold exposure because they are unable to shiver, and they rely on brown adipose tissue for the generation of heat. Maintaining normal body temperature intraoperatively is important because hypothermia increases the incidence of intraoperative and post-

operative complications including bleeding, acidosis, impaired immune function, and delayed wound healing. During anesthesia, children are exposed to all the factors of heat loss, including convection, radiation, evaporation, and conduction. Measures including humidification and warming of inspired air, warmed fluids for intravenous administration, and the use of warming devices such as the BAIR hugger may be used as needed (Pierro et al, 2006; Wetzel, 2007).

KEY POINTS: SURGICAL PREPARATION AND INTRAOPERATIVE CONSIDERATIONS

- In general, SAP is recommended for (1) all surgery in neonates less than 72 hours of age because of possible exposure to maternal pathogens and particularly compromised immunologic capacity, (2) major class II surgery, and (3) all class III and IV surgical procedures; antibiotic use in class I and minor class II operations is based on individual surgeons' preferences.
- The timing of SAP administration is critically important, and the first dose should be administered 30 minutes to 3 hours before incision.
- VTEs in children are rare, but the incidence is believed to be increasing and is bimodal, occurring most often in infants less than 1 year of age and in adolescents.
- Lower rates of SSI are achieved by using clippers or depilatory agents for hair removal immediately before surgery.
- Blood volume in children varies with age, but it can be estimated at 75 to 80 mL/kg.
- The risks associated with blood transfusion are very low; the incidence of transmission of hepatitis B is 1:63,000, of hepatitis C is 1:103,000, and of HIV is 1:450,000 to 1:600,000.
- Infants and children are more susceptible than adults to changes in ambient temperature because they have a relatively large body surface to mass ratio, less insulating tissue such as fat or hair, and limited energy reserves.
- Maintaining normal body temperature intraoperatively is important because hypothermia increases the incidence of intraoperative and postoperative complications including bleeding, acidosis, impaired immune function, and delayed wound healing.

POSTOPERATIVE CARE

A majority of pediatric urologic operations are performed as outpatient procedures, and there continues to be a push to expand the number of these. Routine outpatient urologic procedures include orchidopexy, herniorrhaphy, circumcision, laparoscopic procedures for maldescended testes, and hypospadias repair. Some groups are also performing operations in this manner that were previously performed exclusively as inpatient surgery, such as unilateral extravesical ureteral reimplants (Palmer, 2008). Certainly outpatient surgery has many advantages including cost savings, lessened psychological trauma, fewer nosocomial infections, and faster recovery (Yaster et al, 1994). However, adequate perioperative patient and family education is vital to obtaining good outcomes, and this requires collaborative efforts from the surgeon, anesthesiologist, and nursing staff.

Complications

The vast majority of children who undergo urologic surgery are healthy, and in this population the incidence of serious complications is less than 1% (Hannallah, 1987). A detailed discussion of complications specific to various urologic procedures is beyond the scope of this chapter, but broad postoperative complications will be addressed instead.

TABLE 128-8 Common Causes of Postoperative Fever

SITE	ETIOLOGY	TIME	INCIDENCE	SIGNS/SYMPTOMS	THERAPY
Wind	Atelectasis	24-48 hr	Very common	Cough, shortness of breath, retractions	Cough, deep breathing, incentive spirometry
Wound	SSI	<24 hr-7 days	Rare	Pain, erythema, induration	Antibiotics, open drainage, and debridement
Water	UTI	3-5 days	Very rare in nonurologic surgery; needs to be considered in any surgery involving the urinary tract	Dysuria, hematuria	Remove indwelling catheter as early as possible, antibiotics
Walking	DVT	>3 days	Extremely rare	Swelling, lower extremity pain, superficial venous congestion, palpable cord	Bed rest, elevation, anticoagulation, thrombolytics

DVT, deep vein thrombosis; SSI, surgical site infection; UTI, urinary tract infection.

Modified from Maxwell LG. Postoperative care. In: McInerney TK, Adam HM, Campbell DE, et al, editors. American Academy of Pediatrics textbook of pediatric care. Elk Grove Village (IL): American Academy of Pediatrics; 2009. p. 552–63.

Although not a surgical complication per se, postoperative nausea and vomiting (PONV) is the most common early complication associated with the administration of anesthesia (Maxwell, 2009). PONV is the most common cause of delayed discharge from the PACU and unscheduled hospitalization following outpatient procedures, representing the cause of almost 25% of unplanned admissions (Patel and Hannallah, 1988; Blacoe et al, 2008). The cause of PONV is multifactorial, but some procedures are known to be associated with higher rates, including orchidopexy, which has been associated with a greater than 50% incidence of PONV (Maxwell, 2009). Another significant contributing factor is the use of opioids in the perioperative period. Several measures can be taken for limiting PONV, including avoiding opioids if possible, using antiemetics perioperatively, adequate intravenous hydration with glucose supplementation, and limiting oral intake postoperatively (Maxwell, 2009). The commonly used antiemetics include benzamides (metoclopramide [Reglan]), serotonin antagonists (ondansetron [Zofran]), phenothiazines (prochlorperazine [Compazine], promethazine [Phenergan]), and antihistamines (diphenhydramine [Benadryl]). We most commonly use ondansetron because it is the only antiemetic drug for children that does not routinely result in sedation. Ondansetron is contraindicated in children taking serotonin reuptake inhibitors for migraine headaches. The use of promethazine (Phenergan) in children is strongly discouraged, given the U.S. Food and Drug Administration warning issued in 2006 that warns that it should not be used in children less than 2 years of age because of the potential for fatal respiratory depression. In addition, it should be used with caution in children 2 years of age and older. In general, children in the PACU should not be forced fluids, and the administration of fluids should be based on the child's request. In the setting of PONV, forced fluids to encourage timely discharge will most likely be counterproductive.

Postoperative fever is a common early surgical problem, and its etiology is taught in the first days of medical-school surgery clerkships as the 4 Ws: wind, wound, water, walking. "Wind" refers to atelectasis, "wound" to an SSI, "water" to an infection in the urinary tract (UTI), and "walking" to fever caused by deep vein thrombosis (DVT) in the lower extremities. Fever, defined as greater than 38.5° C rectal temperature, is common within 24 hours of surgery, and fever is usually caused by atelectasis. Pulmonary toilet with deep breathing, coughing, and ambulation is usually effective in otherwise healthy children. In patients too young to participate in pulmonary toilet, measures such as blowing bubbles can be effective. UTI in the setting of urologic surgery is always a concern and needs to be considered. The other causes, SSI and DVT, are rare to extremely rare in the pediatric population. These common

causes are summarized in Table 128-8. In addition, other common causes of fever in children should be considered including URIs, gastroenteritis, and otitis media.

Postoperative SSIs were traditionally characterized as incisional (superficial) or deep, but this fails to consider the total operative site. The CDC has modified the definition of SSIs, which now are reported as Incisional SSI–Superficial versus Deep or Organ/Space SSI (Ziegler et al, 2003; Ashcroft et al, 2005). It is critically important to diagnose early and to intervene promptly to avoid morbidity and even mortality. The wound is examined for classic signs of infection and inflammation, including erythema, edema, tenderness, and warmth. If there appears to be an SSI, a Gram stain and culture should be obtained with a sterile swab. Treatment should be tailored according to the extent of the infection, and it may include oral or parenteral antibiotics, incision and drainage, or extensive debridement. The incidence of SSIs varies from 1% to 11% in clean wounds and from 6% to 21% in contaminated wounds (Ashcroft et al, 2005). In general, most SSIs occur between the fifth and tenth postoperative days. The rare exceptions are *β*-streptococcal, *Clostridium difficile*, and *Clostridium perfringens* (*welchii*) infections, which produce SSIs that can become clinically apparent within 24 to 48 hours postoperatively. Clostridial and streptococcal infections may be life threatening, and children with these develop high, spiking fevers (39° C to 41° C), become irrational, and may develop jaundice (Maxwell, 2009). Table 128-9 provides a summary of SSIs.

Significant postoperative bleeding is rare in pediatric urology. Persistent bleeding at the surgical incision for more than 6 to 8 hours postoperatively usually indicates inadequate hemostasis and is usually a result of a superficial skin artery. The two most common postoperative bleeding situations encountered in pediatric urology involve circumcisions and scrotal hematomas following herniorrhaphy/hydrocelectomy or orchidopexy, with rates of persistent bleeding of approximately 1% to 2% and 2% to 11%, respectively (Caruso et al, 2000; Brisson et al, 2002; Cathcart et al, 2006). Persistent bleeding following circumcision usually responds to direct digital pressure, and reoperation is exceedingly rare. Scrotal hematomas are usually self-limited, and they generally resolve during a period of 4 to 6 weeks. However, fever, erythema of the overlying scrotal skin, tenderness, and progressive enlargement may indicate close monitoring and surgical re-exploration. In patients with thrombocytopenia, prophylactic platelet transfusion is prudent for platelet counts less than 50,000/ μ L (Gmur et al, 1991).

KEY POINTS: POSTOPERATIVE CARE

- PONV is the most common early complication associated with the administration of anesthesia.
- Certain procedures are associated with high rates of PONV; the rate approaches 50% following orchidopexy.
- Fever, defined as greater than 38.5° C rectal temperature, is common within 24 hours of surgery and, as in adults, is usually caused by atelectasis.
- In cases of SSI, it is critically important to diagnose early and to intervene promptly to avoid morbidity and even mortality.
- The incidence of SSIs varies from 1% to 11% in clean wounds and from 6% to 21% in contaminated wounds; most SSIs occur between the fifth and tenth postoperative days.

Outcomes

Conclusion

Laparoscopy was first performed in urology when a cystoscope was used to inspect the peritoneal cavity. This was done for the localization of nonpalpable undescended testes and inspection of the gonads in children with ambiguous genitalia (Cortesi et al, 1976). Although laparoscopy was initially used primarily as a diagnostic modality to identify a nonpalpable testis, it has now expanded to indications for many types of procedures and is currently considered safe. The ability to effectively treat children with minimally invasive surgery (MIS) has been fueled by improvements in instrumentation, robotics, and the creativity of minimally invasive surgeons. Laparoscopic surgery has gained widespread acceptance given the reliability and durability of outcomes. The proposed benefits of laparoscopic surgery over the standard open approach include better cosmesis, increased magnification improving visualization, reduced postoperative pain, and shorter hospital stays (Casale and Kojima, 2009). Complex laparoscopic surgery such as pyeloplasty, orchiopexy, nephrectomy, renal cyst decortication, pyelolithotomy, ureteral reimplantation, and bladder augmentation have all been performed safely and effectively with outcomes at least comparable to those of open techniques (Docimo, 1995; Law et al, 1997; Baker et al, 2001; Ismail et al, 2010).

The technical difficulty and steep learning curve of laparoscopic surgery has contributed to the growing popularity of robotic-assisted surgery (RAS). The da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) is the only currently available system approved by the U.S. Food and Drug Administration (FDA). It provides advantages such as precise exposure and simplification of suturing as a result of movement of the robotic arms in real time with increased degree of freedom and magnified three-dimensional (3D) view (Lendvay et al, 2008a). RAS has the potential to make laparoscopic surgery more accessible to pediatric urologists and to simplify complex upper-tract and reconstructive procedures (Olsen, 2004; Casale, 2009a, 2010). RAS, initially used for pyeloplasty (Casale and Lambert, 2010) and nephrectomy (Patel and Casale, 2007), can be used to perform ureteral reimplantation (Casale, 2011) and more complex reconstructive surgeries including bladder augmentation (Kojima and Casale, 2011) and antegrade continence enema (Gundeti et al, 2013).

One argued disadvantage of conventional pediatric laparoscopy and RAS is the need for multiple incisions that are significant in size in relation to patient size (Casale, 2009b; Tapscott et al, 2009).

Single-incision laparoscopic surgery (SILS) may be advantageous in children, but experience with these novel techniques remains in its infancy.

GENERAL APPLICATIONS OF LAPAROSCOPY

See Table 129-1 and Box 129-1.

ADVANTAGES OF MINIMALLY INVASIVE SURGERY

The goal and promise of MIS is to reduce the morbidity of surgery. The concept of reducing morbidity through MIS falls under four provisions. The first provision is reducing collateral damage to the body wall. Most genitourinary organs are retroperitoneal and hard to access. The incisional length, even total length, is often reduced. We can definitely state that there is nothing therapeutic in a body wall incision; therefore making them smaller will only help.

The second provision is to reduce scars. Port sites, particularly smaller ones, appear to anecdotally undergo wound contraction during the remodeling process so as to be unnoticeable in my experience. In a current study, we are comparing MIS incisions with open incisions over time. Larger linear scars are growing proportionally with the patient, whereas smaller incisions are contracting over time.

The third provision is to reduce the recovery and precautionary period. The advantage of a reduced recovery period is the principal driving force for laparoscopy in adults. This is harder to demonstrate for children, who tend to heal and recover remarkably quickly. Return to work, typically the reported end point of convalescence, is often not at issue; however, it is important to keep in mind that a child's convalescence frequently occupies one or both of the parents. Furthermore, the reduced disruption of the integrity of the body wall reduces the need for limited activity during wound healing—an advantage for the parent who otherwise would need to police the child's activity.

The fourth and final provision relates to speed and efficiency. Although the reputation of laparoscopy is for longer procedures, some of this might be attributed to an artifact of the learning curve. Once proficient, the laparoscopist is usually just as efficient with a minimally invasive approach as with an open approach.

TABLE 129-1 Current Nonexclusive Categories of Laparoscopic Procedures

CATEGORY	DESCRIPTION
Diagnostic	Examination of internal organs (e.g., evaluation of intersex, evaluation of nonpalpable testis, staging)
Extirpative	Removal of an organ when the surgical approach is through a series of port sites rather than an open incision (e.g., nephrectomy, adrenalectomy, orchiectomy)
Reconstructive	Alteration of the urinary tract to approach normal anatomic order or for function (e.g., pyeloplasty, augmentation, catheterizable channels)

BOX 129-1 Current List of Laparoscopic Procedures Performed in Practice

- Radical nephrectomy
- Partial nephrectomy
- Nephroureterectomy
- Heminephroureterectomy
- Antegrade continent enema
- Varicocelectomy
- Pyeloplasty
- Calyceal diverticulectomy
- Uterocalicostomy
- Pyelolithotomy
- Nephropexy
- Renal cyst ablation
- Renal denervation
- Neovagina
- Bladder diverticulectomy
- Partial cystectomy
- Appendicovesicostomy
- Undescended testis
- Autoaugmentation
- Adrenalectomy
- Extravesical reimplant
- Ureteroureterostomy
- Tapered reimplant
- Transvesical reimplant
- Ileocystoplasty
- Sigmoidocystoplasty
- Sacrocolpopexy
- Retroperitoneal lymph node dissection

DISADVANTAGES OF MINIMALLY INVASIVE SURGERY

The Learning Curve

The working environment is different and requires thinking regarding placement of incisions, different presentation of anatomy to the surgeon, and new equipment for the operating room staff to learn. Technical skills require mastery, and it is difficult for experienced surgeons to move from the comfort of the proficient master to join the ranks of the novice surgeon. For those in academic training centers, training residents and fellows can present an unfamiliar challenge, particularly if their exposure is otherwise limited. Tasian and colleagues (2013) showed that fellows can approach

Figure 129-1. Fellow console time consistently decreased when more procedures were performed.

Figure 129-2. Extrapolated learning curve.

near-expert level within the 2-year timeframe of pediatric urologic fellowship. These researchers prospectively collected the surgical console times in 20 consecutive robotic pyeloplasty cases of four pediatric urology fellows who performed 75% or more of the console time. The console times were compared with 20 consecutive robotic pyeloplasty cases in which the attending surgeon alone performed 100% of the console time. They found that the operative times for the cases in which the fellow performed 75% of the procedure decreased with increasing number of procedures performed (Fig. 129-1). Assuming the trend of increasing efficiency continues at the same rate, operative times for fellows are projected to be equal to those of attending urologists once 42 procedures have been performed (Fig. 129-2). They concluded that with the appropriate exposure to robotics, the learning curve for robotic pyeloplasty would be overcome during a 2-year pediatric urology fellowship, enabling newly graduated fellows to be proficient in robotic surgery (Tasian et al, 2013). This of course would translate to other robotic procedures done by the fellows during training. Because the training is not done in a silo, the experience is additive, making the fellow proficient at many cases and truly experienced at robotics overall.

Cost

As a new field with constantly emerging new technology, institutional commitment to the purchase and upgrading of instrumentation is required. Although laparoscopic surgical procedures are

often criticized for higher costs, attention to selection of reusable over disposable instruments can substantially reduce costs (Yung et al, 2010). Behan and coworkers (2011) compared perioperative factors in patients who underwent robotic-assisted laparoscopic and open pyeloplasty, especially with regard to human capital changes, in an institutional cost analysis. Robotic-assisted laparoscopic pyeloplasty in children was associated with human capital gains, such as decreased lost parental wages, and lower hospitalization expenses. Although true cost is difficult to ascertain, we need a true cost analysis to help monitor expenses and ensure cost containment because the expense of delivering high-quality health care is constantly on the rise.

Contraindications to Minimally Invasive Surgery

Contraindications to laparoscopy in infants, children, and adolescents are the same as for any other surgical procedure, except for evidence of limited pulmonary reserve, which may be considered a relative contraindication. If the patient has sepsis, is in shock, or exhibits a coagulopathy, this should be corrected before MIS is contemplated. If surgery is deemed essential under these circumstances, then it probably should be performed using open techniques (Longdon, 2001).

Strong Contraindications

In the pediatric population there are strong contraindications to MIS. The strong contraindications are cardiopulmonary morbidity, uncorrected coagulopathy, and sepsis. The role of laparoscopy in malignant tumors is yet to be defined. Although laparoscopy may play a role in extirpative procedures for renal cell carcinoma or for retroperitoneal lymph node dissection, its role in the management of Wilms tumor or neuroblastoma has yet to be defined. Morcellation of specimens for extraction has raised concerns about accurate pathologic staging; hence, large tumors mandate an incision to retrieve them. In addition, the fragile consistency of the tumor makes it more prone to rupture, which may preclude the use of this technique (Holcomb, 1999).

Size of the Child

The smaller size of children presents a smaller working environment than found in adults after establishment of pneumoperitoneum. Whereas an adult pneumoperitoneum will typically provide a 5- to 6-liter working space, a 1-year-old boy will present a 1-liter intra-abdominal space (Casale, 2010). Furthermore, the limited volume and small working distance on the abdominal wall in a child can significantly limit the mobility of the laparoscopic and robotic instruments, and the chance of port site conflicts or collisions is greater. A difference of a few millimeters can greatly affect the safety and efficiency of the operation, making the location and placement of the robotic trocars critical in children and necessitating slight variations compared with placement in adults. The diminished thickness of the abdominal wall, especially in infants, makes maintenance of insufflation during instrument exchange challenging. Anchoring the trocar to the abdominal wall with a heavy suture will keep the abdominal wall in place if rapid desufflation should occur (Peters, 1996).

TEAM DEVELOPMENT

A consistent minimally invasive team is imperative to the success of any program, especially robotics. The program should be led by a "Surgeon Champion" who is both dedicated and knowledgeable regarding all instrumentation, credentialing, cost, and operating room flow related to the program. Currently there are no guidelines available for the training of nonphysician personnel involved in the program. Two basic principles should encompass a training program: The first is familiarity with the equipment

and troubleshooting, and the second is the ability to perform a specific surgical procedure safely and efficiently (Orvieto and Patel, 2012).

HEMOSTATIC DEVICES

Manual Ligation

Vessels may be ligated with laparoscopic devices that are available in 5- and 10-mm sizes. Laparoscopic tie assisting devices are also available if clips are not preferred. They typically require a 5-mm or larger cannula and either have a cinch knot technology or allow extracorporeal tying and knot placement with a pusher device. Freehand laparoscopic tying can also be performed but is time-consuming and does not seem to be beneficial with the current hemostatic devices available. Laparoscopic stapling devices are available for hemostasis. They are an excellent alternative for large vessels and for transecting thick tissue such as bowel mesentery. The laparoscopic stapling devices require a 10-mm or larger trocar for access and come in different lengths, deployment widths, and angulation capabilities. The tissue or vessel is transected as the staples are deployed. One must ensure that the device completely traverses the target before deployment; otherwise hemorrhage can occur, especially with large vessels or thick vascular tissue. Stapling devices have been routinely used for main organ vessels as well as mesentery with reproducible success. If dividing vascular structures, one must be certain that the device contains vascular and not gastrointestinal staples.

Energy Devices

Care should be taken when dividing tissue or establishing hemostasis with high-energy devices, because injury to adjacent structures is possible. A 3- to 5-mm, right-angled hook cautery is a useful device for dividing tissue and preventing hemorrhage. It is important to make contact with the tissue before activation of the monopolar electrode to avoid arcing of current, which may cause a delayed thermal injury to internal structures. Another form of electrosurgery that is available is use of a bipolar cautery forceps, which allows for greater control of the current than with standard monopolar devices owing to less dispersion of energy. Ultrasonic shear devices use high-frequency ultrasonic oscillation to heat the tissue, forming a coagulum. They come in 5-mm and 10-mm widths. Both the ultrasonic and bipolar vessel sealing devices can be used for vessels up to 5 to 7 mm in diameter. Mishra (2013) performed a meta-analysis of the literature comparing these devices. The analysis found that bipolar devices provided a more secure seal in up to 7-mm vessels; however, the ultrasonic devices had less thermal spread and used less surgical time. Based on the data, he concluded that the decision regarding which energy source to use for each particular part of a specific procedure was dependent on the surgeon's experience.

SUTURING

Intracorporeal suturing requires two needle holders or a needle holder and a grasping device. I favor a 10-cm length of suture with its curved needle directly passed through 5-mm trocars, but not through 3.5-mm trocar unless the curved needle is first straightened. The suture may also be passed through the abdominal wall to avoid the need for a 5-mm trocar if 3-mm or smaller trocars are being used. Laparoscopic extracorporeal assisted tying is possible but requires a large cannula at one of the port sites. There are various automatic suturing devices and suture assistants; however, it is important for the endoscopic surgeon to become proficient with unassisted suturing techniques. This is because suture-assist devices require larger trocars and are more costly than unassisted intracorporeal suturing. Furthermore, the majority of devices have a limited choice of suture material and size, and most are not acceptable for complex delicate reconstruction (Schwab and Casale, 2005).

An innovative technique for intracorporeal suturing for a procedure such as a pyeloplasty is to tie together the ends of two 5-cm segments of 6-0 Vicryl, one dyed and one undyed, both on a small taper needle, before insertion into the peritoneal cavity. The knot tied initially secures the first suture into the renal pelvis and both decreases trauma to the tissue and expedites the anastomosis. The color differentiation facilitates suturing and decreases any confusion and need for repetitive suturing (Farhat and Casale, 2009).

Robotics adds an element of dexterity; seven degrees of freedom are achieved to perform complex manipulation to aid in suturing and intracorporeal tying. The key to a successful robotic execution of suturing is twofold: (1) awareness of the limits in pitch and yaw of the robotic wrists, and (2) visual cues to realize when the suture is tied effectively without breaking it. The latter element comes with practice and experience with the currently available platforms.

ANESTHESIA

Induction and maintenance of anesthesia may be with either inhalational or intravenous agents or a combination of both. Nitrous gas increases bowel distention, potentially bringing the peritoneum closer to the area of dissection for retroperitoneal procedures and decreasing working space in transperitoneal procedures. Also, it is very important to communicate with the anesthesiologist to ensure that during induction, gastric distention with air is addressed immediately after intubation owing to the rapid gastric emptying time of children. This will decrease the amount of air in the small bowel. When the air is left in the stomach and passes to the small bowel, it causes what I call a "pufferfish effect" whereby the distended bowel occupies the majority of the peritoneal cavity, making laparoscopy difficult or impossible (Fig. 129-3).

Intraoperative monitoring should include routine electrocardiogram, noninvasive blood pressure, SpO₂, temperature, end-tidal CO₂, and inspired oxygen concentration (Tobias, 2002). Maintenance intravenous fluid is usually sufficient unless there is unanticipated bleeding. Finally, it is preferable to insert the intravenous line in the arm on the side of the surgery for a patient in the flank position for easy access.

Anesthesia Physiology

Patient positioning during laparoscopic surgery may potentiate the impact of gas insufflation. For instance, Trendelenburg position

Figure 129-3. Distended small stomach after induction of anesthesia. It is imperative to empty the stomach after intubation and before any other manipulation.

during laparoscopy will increase heart rate and vascular resistance while decreasing mean arterial pressure and cardiac output, whereas the opposite effect is seen in reverse Trendelenburg (Logsdon, 2001). In my experience, flank positioning adds further stress, with the left lateral decubitus position producing more significant hemodynamic and respiratory changes than the right flank position, which produces more than the supine position.

Pressure Effects

As gas is placed in the closed space of the operative field, the pressure rises and cardiovascular, pulmonary, and renal effects occur. The heart rate and mean arterial pressure increase while the venous return and cardiac output decrease. These parameters are seen even when pressure is set at a standard working level of 10 mm Hg. Above a level of 15 mm Hg, more profound hemodynamic alterations are anticipated to occur with further decrease in cardiac output. Furthermore, limitation of diaphragmatic mobility may cause respiratory restriction manifesting with increased airway pressure, requiring an increase in the peak end-inspiratory pressure to maintain a set tidal volume. In some cases this can lead to a pneumothorax. Finally, renal effects occur secondary to gas insufflation, manifesting with decreased glomerular filtration rate and urine output. Animal studies have shown that gas insufflation causes renal vein compression inducing decreased renal blood flow, decreased urine output, and diminished creatinine clearance (Holcomb, 1999; Peters, 2000). These effects do not appear to cause renal damage in humans, however.

Absorption Effects

Insufflated CO₂ is absorbed into the blood by diffusion that is limited and determined by many variables. Most important are the pressure differential and the cross-sectional area of the absorbing surface. The pulmonary effects are increased CO₂ retention and increased end-tidal CO₂, exacerbated by decreased functional residual capacity and decreased diaphragmatic excursion. The hemodynamic effects of hypercarbia are increased heart rate, vasodilation, increased cardiac contractility, and increased intracranial pressures. Although in healthy children there is little if any added cardiorespiratory risk from laparoscopic procedures, children with cardiopulmonary compromise require close and careful monitoring (Tobias, 2002) (see Table 129-1).

THE DIFFERENT APPROACHES: TRANSPERITONEAL VERSUS RETROPERITONEAL

Laparoscopic approaches provide exceptional exposure rivaled only by a complete abdominal laparotomy incision because the intraperitoneal space is large. Trocar selection is at the discretion of the surgeon and should be a balance of minimizing the incision without compromising the access needed for the correct size equipment to complete the procedure safely and efficiently. When deciding on making the incision for the trocar, the length of the incision is very important. Blinman (2010) described the wound tension of incisions, stating that tension rises nonlinearly with increasing wound length. The total tension across multiple incisions is less than the total tension for an incision of the same total length. For example, a 2-cm incision has 2.7 times more wound tension than three 5-mm incisions. Two 3-mm incisions have less than one 5-mm trocar. He also describes that the correct length of the incision of a trocar's width is half the circumference as with any cylinder. I use the angle at the tip of the trocar where it has its maximal open distance as the proper incision length because this angle causes the maximal length to closely approximate half of the trocar's circumference. This length allows the correct trocar incision where tension is minimized but still would hold the trocar in place without dislodgement (Fig. 129-4 and Table 129-2).

Figure 129-4. The distance between the widest portion of the angled opening of the trocar is an easy approximation of the length needed for half the circumference of the cylindric trocar to have an adequate incision with minimal tension and looseness.

TABLE 129-2 Comparison of Retroperitoneoscopy and Transperitoneoscopy

RETROPERITONEAL	TRANSPERITONEAL
Avoids need to retract intestines	Roll and Trendelenburg often all that is needed
Great vessels typically serve as the medial boundary	Intestines in working environment
Less traditional; lower acceptance	“Tried and true”
Lower incidence of port site problems	Higher incidence of port site–associated complications (e.g., hernia, enteric fistula)
Lower hernia risk	Higher hernia risk
Does not decrease risk for injury of organs such as colon	Quickest “exit” strategy for emergency
Steps to get to the retroperitoneum allow laparoscopic “warm-up” techniques	“Warm-up” exercises before the actual procedure are possible because of larger working space

Patient Preparation

I prefer to have the child take an age-appropriate dose of magnesium citrate 2 nights and 1 night before surgery. If the child cannot take magnesium citrate, then I prefer a liquid diet the day before surgery to help with any excess stool in the colon. True bowel preparations are not needed unless bowel is going to be used during the surgery. In that instance, admission the day before with a proper bowel cleanout would be recommended. Nonsteroidal anti-inflammatories should be avoided for 2 days before surgery and aspirin for 7 days. Taking more than 3 g of fish oils per day might keep blood from clotting and can increase the chance of bleeding, so fish oils should be discontinued 1 week before surgery.

Transperitoneal Approach

Positioning

For upper tract transperitoneal procedures, positioning the patient in a flank or modified flank position at the edge of the table is helpful, although these procedures can be performed with the patient supine with rotation of the operative table. Edge positioning

allows the surgeon full access to the abdominal cavity without limitations caused by the edge of the table. For the modified flank, a roll should be placed under the torso to provide a 60-degree patient angulation from the table. The patient should be secured so the table may be repositioned as necessary during the procedure. The main monitor should be placed on the lesion side of the operative table, with a slave monitor behind the surgeon. All cables, lines, and wires for the instruments should preferably go off the opposite side to the surgeon. This positioning is used for the majority of renal interventions such as nephrectomy, heminephrectomy, pyeloplasty, and other renal extirpative and reconstructive procedures. The transabdominal approach also allows access to the anatomic pelvis by placing the camera through the subcostal port and instruments through the umbilical and lateral ports.

For lower transperitoneal procedures in infants, it is most convenient to position the patient at the foot of the bed, across the bottom, and to stand at the side of the bed (at the patient's head) to operate (Holcomb, 1999). This is an optimal approach to the bladder. For older patients a midtable, supine position with a sacral roll to thrust the pelvis up is preferable. Usually the side opposite the lesion is chosen, and the telescope is placed centrally in or near the umbilicus. The instrument trocars are placed lateral to the rectus muscle usually at the level of the anterior superior iliac spine. The monitor should be at the foot end of the operative table. Only one monitor is necessary in this scenario. All cables, lines, and wires should be off the foot of the bed for optimal ergonomics. This approach is extremely helpful for gynecologic and urologic procedures in the pelvis.

The transvesical approach requires cannula fixation so that the bladder mucosa does not strip and dissect away from the detrusor muscle. One way to achieve this is to perform a cystostomy using cystoscopic visualization to ensure the mucosa is attached at the skin incision to help hold the bladder wall and mucosa to the anterior abdominal wall. A balloon-tipped cannula may also be helpful here, but the size of the balloon tip may impair instrument manipulation in a small child.

If a robot is being used, the room setup must allow the robot to approach the patient on the side of the target organ. For example, if the left kidney is to be operated on, the robot must come over the patient from the left. If the bladder is the target organ, the robot should come from the foot of the bed. For bladder procedures it can come directly at the foot of the bed or on an angle to the pelvis from the foot of the bed, aiming at the contralateral shoulder of the position. For example, if the robot is coming from the right foot of the bed, aim the robot at a 45-degree angle toward the left shoulder.

Laparoscopic Access Techniques

Transabdominal access is best achieved through the umbilicus with use of either a Veress or an open technique whereby the umbilicus is lifted using an Allis clamp, then with a No. 11 blade the skin and subcutaneous tissue are incised and the peritoneum is entered. Instruments can be placed directly through a stab wound without the need for a trocar if the surgeon does not anticipate repeatedly withdrawing and reinserting instruments through this site (Lobe, 1998; Holcomb, 1999; Peters, 2000; Tam, 2000; Telsey and Caldamone, 2001; Blinman, 2010).

In infants and thin children, the laxity of the abdominal wall might allow large trocars or heavy instruments to compress the abdominal wall, obscuring vision and limiting CO₂ distention. Once access has been attained, sometimes bowel, bladder, or other structures can obstruct the view. It can be helpful to pass one or more sutures through the abdominal wall, through the structure, and back out through the abdominal wall for retraction. These can be tied to a self-retaining retractor or can simply be tied at the distended abdominal wall if that is sufficient (Holcomb, 1999).

Step-by-Step Access Procedure

See Boxes 129-2 and 129-3.

BOX 129-2 Steps in Veress Access

1. Position patient.
2. Patient secured with tape for Trendelenburg and airplane roll of operating room table to 30 degrees each. Table should be moved through a full range of motion (table run to limits of motion), particularly with larger patients, to ensure they are stable in position.
3. Urethral catheter—if orchiopexy, varicocele ligation, or bladder manipulation, place on field after preparation. In male retroperitoneal cases, one can consider scrotal wrap to prevent pneumoscrotum.
4. Surgical preparation and drape, full access to abdomen (and perineum if Foley manipulation required, varicocele, or orchiopexy).
5. Assemble and test lens, camera (white balance), light source, monitor, insufflator, electrocautery generator. Secure cords to table. If a robot is being employed, ensure the team has checked the system.
6. Warm lens (I prefer a warming bath).
7. Supraumbilical or infraumbilical incision with a length determined by the trocar width as previously described. In infants (especially) and children, the peritoneum is not well affixed to the abdominal wall and therefore the access to the abdomen through a supraumbilical position, above the fixation point of the peritoneum to the umbilicus, reduces potential for preperitoneal insufflation.
8. Abdominal wall lifted at the umbilicus; in thicker-walled patients (e.g., a muscular adolescent), a towel clip or heavy suture or Kelly clamp can be used to lift the abdominal wall.
9. Veress held in “dart fashion” with thumb, index, and middle fingers; ball of hand on patient’s upper abdomen.
10. Forefingers and thumb advance Veress through stab wound and abdominal wall.
11. Confirm position with either pressure via insufflator (my preference) or a “drop test”—aspirate (no succus entericus, blood, urine), inject with 5 mL saline, withdraw (return of fluid suggests preperitoneal position), reinject 1 to 2 mL to break potential air locks, release syringe, fluid should “drop.”
12. Insufflate—confirm low pressure, switch to high flow and to pressure of 15 to 20 mm Hg. For initial port placement, 15 mm Hg in children, 20 mm Hg in adults.
13. Insert trocar with hand braced to prevent any uncontrolled advance of trocar.
14. Decrease pressure to 8 to 10 mm Hg. The right pressure is enough to see. Added pressure does not help visualization and will only add to the anesthetic effects of insufflation.
15. Insert lens.
16. Survey abdomen for injury.
17. Secure trocar—suture to abdominal wall.

Direct Access

Direct access offers another means of entry via an incision sized to the port made at the umbilicus. The abdominal wall is supported and lifted upward. The trocar is placed directly into the abdomen. Proponents argue that the use of a single blind step is preferable to two blind steps in Veress access. The access can be done blindly or under direct visualization through a trocar designed to traverse tissue with a camera inserted through its obturator.

Midline or off-midline visual trocar access employs various optical trocars, such as a VisiPort (Covidien, Norwalk, CT) or Opti-View (Ethicon, Cincinnati, OH), which range from 5 mm to

BOX 129-3 Steps for Open Access

- 1-8. Same as for Veress access
9. Periumbilical incision of 15 to 20 mm in length created with No. 11 blade. The incision should allow insertion of Sims retractors to visualize the fascia.
10. The subcutaneous tissue is spread and incised to the level of the fascia. Two stitches are placed in the fascia to secure it. The suture is cut to length to allow it to be tied, then lifted into the wound. The fascia is incised between the stitches.
11. The preperitoneal fat is spread and the peritoneum identified, elevated into the wound, and opened.
12. The port is inserted into the peritoneal cavity under vision. Blunt-ended trocars are typically used. One problem is that a 10- to 12-mm port, typically used in this setting, obscures the view into the “hole,” preventing clear vision of the actual insertion step. The use of a Step trocar and sheath system allows the surgeon to place the 2-mm sleeve into the cavity under direct vision then expand it to size.
13. The fascial sutures are snugged at the fascia and held in a Rommel fashion then secured to the port.
- 14-17. Same as for Veress access.

12 mm. These allow the tissue beneath the end of the trocar to be seen. Off midline, an incision is made in the skin typically overlying the rectus muscle, and the trocar is inserted. The muscle is observed as the trocar advances. When the port is placed through the rectus the posterior sheath is encountered just deep to the rectus. The port is advanced to a position just beyond the rectus, then insufflation is begun. The same is done through the umbilicus, but of course the layers are different. Once the rectus midline has been passed, the surgeon will visualize the peritoneal lining to enter the abdomen.

When the initial access is lateral to the rectus, the location of the port is followed through the orientation and layer number of the muscle fibers. It is important to remember that at the lateral border of the rectus all three muscle layers (external oblique, internal oblique, and transversus) may not be present. Familiarity with the orientation of the fibers is paramount for safe entry. Briefly, the external oblique courses from a superior lateral to inferior medial position, internal oblique from inferior lateral to medial, and transversus lateral to medial. A thorough understanding of this anatomy and variations likely to be encountered is needed for this access (Box 129-4).

Retroperitoneal Laparoscopic Approach (Box 129-5)**Advantages**

The retroperitoneal approach mimics the open urologic surgical procedure through the retroperitoneum. This is a direct approach to the organs of the genitourinary tract that requires less dissection of the colon or the spleen to expose the kidneys and adrenals and is a familiar region to the urologist. The landmarks are the same as in open retroperitoneal surgery. The retroperitoneal approach is also possible in the face of previous transperitoneal surgery done via either open or laparoscopic technique. It is my experience that the trocar sites have fewer postoperative hernias than do open incisions. Once retroperitoneal access is gained, the view of the posterior surface of the kidney, hence access to the renal hilum, is rapid.

Disadvantages

The disadvantage of retroperitoneal laparoscopy is that manipulation of instruments may be initially difficult owing to a restricted

BOX 129-4 Steps for Direct Access

1. Position patient.
2. Patient secured with tape for Trendelenburg and airplane roll of operating room table. Confirm full range of motion.
3. Surgical preparation and drape, full access to flank and back.
4. Assemble and test lens, camera (white balance), light source, monitor, insufflator, electrocautery generator. Secure cords to table.
5. Lens placed in VisiPort—refocus (lens effect of device).
6. Incision as described previously.
7. VisiPort placed in wound; orient blade parallel to anticipated muscle layer 8.
8. Advance to fascia; incise.
9. Incise and spread muscle.
10. If multiple layers of muscle, reorient blade for each sequential layer.
11. At end of “last layer” (transversalis for flank, lumbodorsal fascia prone), advance slightly with single activation.
12. Gently advance VisiPort; observe retroperitoneal fat or bowel.
13. Insufflate—low pressure.
14. Balloon or lens—dissect space if retroperitoneal.
15. Remove optical trocar piece, reinsert lens, refocus.
16. Survey for injury.
17. Secure trocar—suture to abdominal wall.

BOX 129-5 Relative Contraindications to Retroperitoneal Surgery

1. Prior retroperitoneal scar (kidney surgery, kidney biopsy, or pyeloplasty)
2. Previous infectious or inflammatory retroperitoneal process (xanthogranulomatous pyelonephritis) except for surgeons experienced with this approach

working space. For instance, in reconstructive surgery such as a pyeloplasty, suturing and knot tying may be difficult. In ablative surgery, the degree of technical difficulty increases in the presence of large specimens. Also, achieving anatomic orientation may initially be a challenge for the inexperienced laparoscopist.

Anatomic Considerations for Retroperitoneal Laparoscopy

An understanding of the retroperitoneal surgical anatomy is mandatory before embarking on retroperitoneoscopic surgery. The boundaries of the retroperitoneal space are as follows:

1. Posteriorly and laterally: the paraspinous, psoas, and quadratus lumborum muscles, which are anatomically fixed structures
2. Anteriorly: the mobile posterior parietal peritoneum and its contents
3. Superiorly: the diaphragm
4. Inferiorly: contiguous with the extraperitoneal portions of the pelvis

Step-by-Step Retroperitoneal Access Procedure

Patient Positioning. Although a retroperitoneoscopic approach may be accomplished with the patient prone, I prefer the flank position for renal cases because it increases the anteroposterior dimensions of the retroperitoneal space and displaces the peritoneal

reflection anteriorly, decreasing the chance of inadvertently opening it. The prone position for retroperitoneal access is used for retroperitoneal lymph node dissection only (Box 129-6).

Insert the trocar toward the area of dissection; if the trocar is advanced away from the site of dissection, this might result in the following:

1. Constant tension on the skin during surgery, making maneuvering difficult
2. Greater chance of gas leakage at the trocar site

In the event that more than three ports are required, laparoscopic guidance and bimanual palpation are recommended for accurate placement. The placement of this accessory port varies from case to case and patient to patient owing to the differences in the retroperitoneal space.

TROUBLESHOOTING THE ROBOTIC APPROACH**Robotic Port Placement (Box 129-7)**

Port placement for both robotic and pure laparoscopic procedures will vary with the anatomic organ. Laparoscopy adds an element of surgeon ergonomics whereby a triangulation of the trocars is typically easier on the posture of the surgeon. The robotic platform works better when the trocars are in a straight line with the ports at a minimum of 4 cm apart from one another. It is my experience that this configuration virtually eliminates collisions of the robotic arms. Figures 129-5 through 129-8 show my preferred port sites for the specified procedures. Patient positioning is the same for pure laparoscopic and robotic-assisted procedures.

Robotic Visualization

The visualization offered by the robotic platform is an advantage that is not possible with pure laparoscopy. It allows 3D visualization as well as digital zooming. However, because it is a more complex visual aid, it requires more troubleshooting than just the average laparoscope. The issues that arise from the camera fall into six distinct categories: restricted movement; restricted excursion; “fuzzy” vision; “cloudy” vision; dark fields; and inability to focus. Each is addressed in Box 129-8.

LAPAROENDOSCOPIC SINGLE-SITE SURGERY

Although in its infancy, laparoendoscopic single-site surgery (LESS or SILS) has the potential to minimize the number of incisions while maximizing intracorporeal access. The theoretical advantage of LESS is that an entire procedure can be done using an incision that would have been necessary for specimen removal in conventional laparoscopy. The umbilical location of the incision improves cosmesis; however, the advantages of LESS compared with conventional laparoscopic surgery have yet to be proved. It also is contrary to the current literature of wound tension and healing presented earlier. In most cases of LESS for the pediatric patient, an accessory port is used. Some argue that this form is just an awkward way to perform pure laparoscopy because the added trocar negates the LESS advantage. A limited number of case reports and small series have described the use of LESS surgery for pediatric urology procedures including nephrectomy (Lobe, 1998; Koh et al, 2010; Marietti et al, 2010; Vricella et al, 2010; Ham et al, 2011), nephroureterectomy (Koh et al, 2010; Ham et al, 2011), and pyeloplasty (Tugcu et al, 2010, 2011).

Access is obtained using an open Hasson technique by way of the umbilicus, and a single-port access device is deployed. Two commonly employed ports include the Olympus TriPort (Olympus, America, Melville, NY; Advanced Surgical Concepts, Wicklow, Ireland) and the Covidien SILS port (Covidien). The Olympus port includes an associated introducer, which allows for placement of the single port using a 10- to 15-mm umbilical incision. The SILS port can be placed through an incision as small as 15 mm, and it

BOX 129-6 Step-by-Step Retroperitoneal Access

1. The patient is positioned in the full 90-degree flank position as close to the posterior edge of the table as possible.
2. The table is flexed and the kidney rest elevated.
3. Pressure points are padded and an axillary roll is placed.
4. The patient should be taped to the table using 3-inch adhesive tape placed across the shoulder and the hips so that they will remain secured while the table is moved during the surgery.
5. I prefer to have the surgeon and assistant standing on the same side; therefore we use only one monitor to facilitate eye-hand coordination between assistant and performing surgeon.
6. Open (Hasson) technique provides visual guidance. Because children have a small retroperitoneal space and close proximity between the abdominal wall and the major vessels, the closed technique is not recommended. In addition, because there is no actual preexisting retroperitoneal space, the placement of a Veress needle is not precise and may cause injury to either the great vessels or the pneumoperitoneum.
7. Midaxillary line: a 1-cm long incision is made 1 to 2 cm below the tip of the 12th rib.
8. The muscles are split in the direction of their fibers, and then the lumbodorsal fascia is incised to enter the retroperitoneum.
9. Development of the retroperitoneal space using a blunt instrument or the balloon dissector is up to the surgeon. Although commercial balloon dissectors are readily available, an inexpensive balloon can be made using the finger of a surgeon's glove tied around a catheter. The balloon is inserted anterior to the psoas muscle and outside the Gerota fascia, and approximately 400 to 500 mL of air is used to inflate the balloon, creating the space. Another technique described by [Farhat and Casale \(2009\)](#) is to introduce a wet gauze close to the posterior muscular wall to create the retroperitoneal space.
10. Ensure the primary trocar is inserted in the correct space. If too far medial, it will result in peritoneal entry or colon injury; entering posteriorly in the quadratus or psoas muscles may cause bleeding.
11. Create the retroperitoneal space outside the Gerota fascia; dissect the peritoneum medially. I create the retroperitoneal space using blunt dissection. Through the primary incision and with the psoas muscle as a reference point, a 10-mm trocar with the laparoscope (0 degree) is inserted to confirm correct placement. Initially, the posteroinferior aspect of the Gerota fascia and the lower pole are visualized. Identification of the psoas muscle posteriorly is crucial. Anteriorly, the edge of the peritoneum is identified and swept medially to expose the underside of the transversalis fascia.
12. Avoid tearing the peritoneum by dissecting it medially with the laparoscope in a lateral-to-medial fashion close to the abdominal wall to expose the internal surface of the transversalis muscle.
13. Place the posterior secondary port approximately midway between the 12th rib and the iliac bone, and lateral to the border of the paraspinal muscles. With use of a grasper through this trocar, the peritoneum is further mobilized medially to create the pelvic extraperitoneal space.
14. Place the anterior secondary trocar at the anterior axillary line 2 cm superior to the iliac crest. The two secondary ports should be inserted as far apart as possible to improve ergonomics.

BOX 129-7 Nuances for Robotic Trocar Placement

- Place the umbilical trocar in the superior aspect of the umbilicus in smaller children.
- Mark ports 4 cm apart after the abdomen is insufflated (becomes extremely important in the infants).
- Anchor skin at port sites to trocar to prevent abdominal wall slippage off trocar during moments of desufflation.
- Always "burp" the camera and working ports. Burping the ports encompasses holding the trocar and pressing the set joint button on the robot while lifting both the arm and the trocar together to increase the distance between the trocar and target organ. This maneuver allows further excursion of the robotic instruments, which becomes important during procedures on infants.

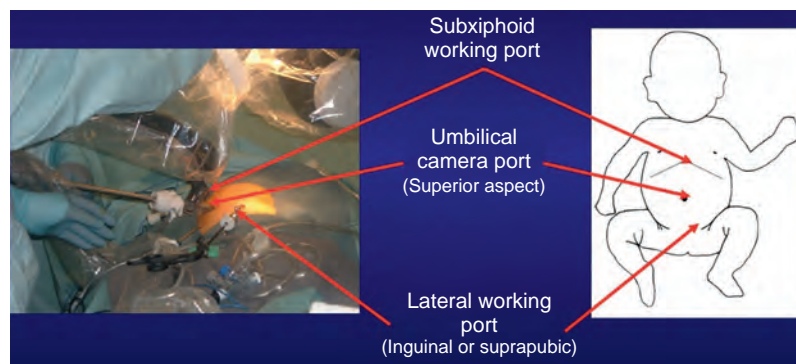

Figure 129-5. Schematic of renal port sites for robotic cases.

allows access for three 5-mm cannulas or two 5-mm cannulas and one 12-mm cannula. All ports are single-access multichannel laparoscopic ports. A combination of flexible forceps and scissors and conventional laparoscopic (straight) instruments can be used. Procedures are performed in similar fashion to conventional laparoscopy.

POTENTIAL COMPLICATIONS AND SOLUTIONS

Laparoscopic surgery always carries the risk of injuries. These are more common during the learning curve, and increasing experience may lead to a decrease in complication rates. The overall complication rate in laparoscopy has recently been shown by Peters and

colleagues to be 5.4%, with the rate of major complications being 1.2%, of which 0.4% necessitate surgical intervention (Passerotti et al, 2008). The group also concluded that the greatest predictor of complications was the surgeon's laparoscopic experience.

Vascular

If bleeding occurs, usually coagulation and pressure are sufficient for control during the procedure (Mishra, 2013). Severe vascular injuries are rare and may necessitate open conversion. However, not all vascular injuries occur during the laparoscopic portion of the operation. Great vessel injury may occur from laparoscopic access or dissection. In children the distance between the abdominal wall and the great vessels may be as little as 5 cm. To avoid vascular injury secondary to access, it is advisable to tailor the length of the trocars to the patient age and body habitus. During access, vascular injuries might manifest with either bloody return from the injury site or rapid deterioration of the hemodynamic status of the patient. Once extensive vascular injury is suspected, the trocar should be left in place and an open exploration should be performed. If a major vascular injury is encountered during dissection, laparoscopic compression should be maintained while gaining open access. If the vascular injury during dissection is minor, such as laceration to the gonadal vessels or adrenal vessels, hemostasis can potentially be achieved laparoscopically through the use of clips, staples, or ligation. Vascular entry of insufflation can be catastrophic. If vascular entry is noted after insufflation has started, the patient should be placed in reverse Trendelenburg position with right side up to trap the air embolus in the right atrium. The air can then be retrieved with catheterization aided by transesophageal ultrasound.

Figure 129-6. Robotic bladder access port sites. APV, appendicovesicostomy.

Organ Injury

Bowel injury is a risk of both transperitoneal and retroperitoneal laparoscopy. Because bowel is out of sight during retroperitoneal procedures, injuries may occur during trocar insertion, dissection secondary to lacerations, or thermal injuries from electrocautery.

If bowel injury is identified during laparoscopy, it is best dealt with at the time of occurrence. If the surgeon is laparoscopically skilled, the bowel may be repaired using a laparoscopic approach; otherwise a general surgery consultation is recommended. I believe that a contaminating small or large bowel injury is best handled by open repair with or without proximal fecal diversion. In addition, injuries to the liver or spleen may occur during laparoscopic retroperitoneal surgery. If the injuries are superficial, attempts to control the injury laparoscopically with gel foam or with an argon beam coagulator may be undertaken. Otherwise, open exploration is recommended. Because these injuries may go unnoticed, inspection of the peritoneal or retroperitoneal space on access and before exiting is of paramount importance. If a bowel injury goes unrecognized at the time of surgery it will usually manifest at 2 to 3 days postoperatively as a result of thermal injury with abdominal pain, particularly at the port sites, ileus, fever, and leukopenia. The physical examination findings are usually out of proportion to the pain. Causes are usually from cauterizing instruments, but injury can also arise from the heat generated by the camera.

Infection

Wound infection should occur in less than 5% of patients and is managed either by a 7- to 10-day course of antibiotics that cover common skin organisms or sometimes just by simple wound drainage. In my experience, the umbilicus appears more susceptible to infection than the other port sites.

Intraoperative urinary cultures should always be obtained in case a postoperative urinary tract infection develops. Postoperative urinary infections should be managed with 10 to 14 days of antibiotics once susceptibilities have returned. Urinary drainage might be indicated, because all these infections should be considered complicated and not simple urinary tract infections. If signs of sepsis continue despite proper urinary drainage and antibiotics, an abscess or infected urinoma should be assessed with an ultrasound and/or computed tomography (CT) scan. There are no current data available to determine whether or not prophylactic poststent antibiotics are beneficial.

Urine Leak

Because the urinary tract is manipulated, especially in reconstructive procedures, there is always a risk of urinary leakage from the target

Figure 129-7. Extravesical ports and intravesical ports. The use of intussuscepted trocars might help with the intravesical approach because of the limited excursion of the instruments and camera resulting from limited working space of the pediatric bladder.

Figure 129-8. Infant port site positioning for bladder access.

organs. Intra-abdominal urine leak usually results in severe ileus, pain, and acute abdominal distention, which may include nausea and vomiting. The physical examination typically reveals a tense abdomen with tympanic bowel only on the anterior midline of the abdominal cavity. On abdominal x-ray examination, the bowel is usually centralized and surrounded by a ground-glass appearance, especially in the right and left colonic gutters. Urinary diversion is paramount, and, depending on the location of the leak, a stent, stent and bladder drainage, or percutaneous upper tract diversion with nephrostomy tubes might be necessary. Causes of urinary leakage can be from an anastomosis; an unrecognized kidney, bladder, or ureteral injury from dissection or cautery; or stent migration in the setting of pyeloplasty or ureteral reimplantation, for example. Stent migration can occur intraoperatively when the stent is not positioned correctly, or the stent can be dislodged with removal of the urethral catheter. It has been helpful in my experience to turn the urethral catheter just before removal to help dislodge a stent if it becomes entrapped in the eye of the catheter. If stent location is questioned, one can fill the bladder with methylene blue to see if it comes up the stent during upper tract surgery. However, if there truly is a concern, intraoperative imaging is paramount before waking the patient from general anesthesia.

Hernias

Typically, hernias at the port sites require operative intervention on an emergent basis. Port site hernias may manifest as a bulge or tenderness at one of the port sites, but initially can just be continuous leakage of serous fluid. If findings are not definitive on physical examination, ultrasound can help diagnose a hernia. The size of the trocar does not preclude hernia in children, and port site herniation may occur in 3-mm and 5-mm trocar sites. Most of the time, it is the omentum that herniates through the port site. A few published reports state that 3- and 5-mm trocar sites should be closed; however, no definitive algorithm exists. It is at the discretion of the surgeon whether closure of these wounds is warranted (Peters, 1996; Farhat and Casale, 2009). Nonetheless, because trocar site closure in the pediatric patient is relatively straightforward, one should consider it in order to prevent the potential complication of herniation (Farhat and Casale, 2009). Internal hernias are rare but could theoretically occur at the window in a mesenteric defect if inadvertently created when reflecting bowel, or from intra-abdominal adhesions.

OUTCOMES

The implementation of MIS in children, while at first met with reservations, is now becoming embraced by pediatric urologists (Lee et al, 2009; Koh et al, 2010; Tugcu et al, 2010; Vricella et al, 2010; Ham et al, 2011; Tugcu et al, 2011). The reason for this

BOX 129-8 Categories of Issues with Robotic Visualization

RESTRICTED MOVEMENT

- Camera is bumping into something such as the Mayo stand or another arm.
- It can be restricted by the plastic drape.
- In the standard systems, the camera mount may have come undone from the arm

LIMITED ZOOM

- Make sure the trocar is seated at the limit of the camera mount.
- Make sure the trocar is inserted appropriately at the fascia level. For an obese individual, the camera trocar might have to be inserted farther in than the guide markers.

“FUZZY” VISION: EDGES ARE NOT CRISP OR ARE OUT OF FOCUS

- Try closing one eye then the other to see if there is a difference. If not, then focus. If there is a difference then do the following:
 - Check for a smudge on the lens.
 - If both are not focused after cleaning, try calibrating again.
 - If one is focused but becomes out of focus when you focus the other eye, then you need a new scope.

“CLOUDY” VISION: A FILM ACROSS THE VISUAL FIELD

- First, clean the end of the lens.
- If still present, check for condensation between the lens and the camera.
- If it continues, check the surgeon console because cleaners can cause a film on the eyepiece in the surgeon console. Do not clean with alcohol. Use warm water and dry thoroughly.

DARK VISION

- From the outset:
 - Have the assistant look at the light coming out of the lens.
 - Check cord to see if it is bright. If not, you need a new cord. If yes, you need a new lens.
- During the procedure:
 - Make sure the light is turned up all the way.
 - Check the bulb life.
 - Make sure the cord is pushed in all the way.
 - In the standard model, confirm that the black balance was done.
 - Still dark despite all these efforts? Turn up the gain; this is not a long-term solution, and the problem should be addressed before the next case.

evolution might be the improved instrumentation, but the current armamentarium available is far from perfect for the pediatric patient. The instruments are adapted from the adult patient to be used in pediatrics, but pediatric-specific instrumentation is in its infancy. The true movement in this evolution is that despite some of the instrument deficiencies, pediatric urologists have been able to mimic the gold standard open success rates and operative times (Farhat and Casale, 2009). Table 129-3, from Tomaszewski and colleagues, summarizes some of the outcomes in the literature of minimally invasive procedures (Lee et al, 2009). One can infer from the data that it is at centers of excellence with surgeon champions where these outcomes are possible. However, because these are teaching institutions, if we perform our duty as mentors properly

TABLE 129-3 Current Robotic Series Outcomes

PROCEDURE	SERIES	n	MEAN/MEDIAN (RANGE) AGE (yr)	APPROACH	MEAN OR TIME (min)	MEAN LOS (day)	COMPLICATIONS (n)	SUCCESS RATE (%)
Pyeloplasty	Atug et al, 2005	7	13.0 (6-15)	TP	184 (165-204)	1.2	1	100
	Yee et al, 2006	8	11.5 (6.4-15.6)	TP	363 (255-522)	2.4	1	100
	Lee et al, 2006	33	7.9 (0.2-19.6)	TP (32), RP (1)	219 (133-401)	2.3	1	93.9
	Kutikov et al, 2006	9	0.5 (0.3-0.7)	TP	123	1.4	0	100
	Olsen et al, 2007	67	7.9 (1.7-17.1)	RP	143 (93-300)	2.0	12	94
	Franco et al, 2007	15	11.9 (4.0-18.0)	TP	223 (150-290)	NR	4	NR
Ureteral reimplantation	Peters and Woo, 2005	6	(5-15)	Vesicoscopic	NR	(2-4)	1	83.3
	Casale et al, 2008b	41	3.2 (1.3-6.8)	Extravesical	2.33 (1.4-3.2)	1.1 (0.8-1.4)	0	97.6
Partial nephrectomy	Pedraza et al, 2004a	1	4	TP	440	2	0	NR
	Olsen and Jorgensen, 2005	14	4.9 (0.5-20.2)	RP	176 (120-360)	1.0 (1.0-4.0)	3	NR
	Lee et al, 2009	9	7.2 (0.5-16.5)	TP	275 (170-417)	2.9 (1.9-4.8)	2	NR
Ureteroureterostomy	Kutikov et al, 2007	2	8.0 (6-10)	TP	NR	NR	0	100
	Passerotti et al, 2008	3	9.5 (4.7-14.3)	TP	244 (240-251)	3.5 (2.4-4.3)	0	100
Ureterocalicostomy	Casale et al, 2008a	9	6.5 (3-15)	TP	168 (102-204)	0.9 (0.7-1.1)	0	100
Appendicovesicostomy	Pedraza et al, 2004b	1	7	TP	360	4	0	NR
(+ augmentation + ileocystoplasty)	Gundeti et al, 2008	1	10	TP	600	5	0	NR
(+ ACE)	Thakre et al, 2008	1	10	TP	200	5	0	NR
(+ ACE)	Lendvay et al, 2008b	1	9	TP	480	5	1	NR
Pyelolithotomy	Lee et al, 2007	5	16.6 (10.2-23.2)	TP	315 (165-465)	3.8 (2.3-5.7)	1	75 (stone free)
Bladder neck sling	Storm et al, 2008	2	9.5 (9.0-10.0)	TP	189 (170-208)	3 (2-4)	0	100

ACE, antegrade continent enema; LOS, length of stay; NR, not recorded; OR, operating room; RP, retroperitoneal; TP, transperitoneal.

From Tomaszewski JJ, Casella DP, Turner RM 2nd, et al. Pediatric laparoscopic and robot-assisted laparoscopic surgery: technical considerations. J Endourol 2012;26(6):602-13.

KEY POINTS

- The proposed benefits of laparoscopic surgery over the standard open approach include better cosmesis, increased magnification improving visualization, reduced postoperative pain, and shorter hospital stays.
- In the pediatric population there are strong contraindications to MIS. The strong contraindications are cardiopulmonary morbidity, uncorrected coagulopathy, and sepsis. The role of laparoscopy in malignant tumors is yet to be defined.
- With regard to learning curve, assuming a trend of increasing efficiency continues at the same rate, operative times for fellows are projected to be equal to those of attending urologists after 42 robotic pyeloplasties have been performed. Because the training is not done in a silo, the experience is additive, making the fellow proficient at many cases and truly experienced at robotics overall.
- A successful minimally invasive program, especially if it includes robotics, should be led by a “surgeon champion” who is both dedicated and knowledgeable regarding all instrumentation, credentialing, cost, and operating room flow related to the program.
- With regard to anesthesia effects, the heart rate and mean arterial pressure increase while the venous return and cardiac output decrease. The renal effects occur secondary to gas insufflation manifested by decreased glomerular filtration rate and urine output.
- With regard to the different approaches (transperitoneal versus retroperitoneal):
 - The total tension across multiple incisions is less than the total tension for an incision of the same total length.
 - The correct length of the incision of a trocar’s width is half the circumference as with any cylinder.
- Issues related to complications include the following:
 - The overall complication rate in laparoscopy has recently been shown to be 5.4%, with the rate of major complications being 1.2%, of which 0.4% necessitate surgical intervention.
 - Vascular entry of insufflation can be catastrophic. If vascular entry is noted after insufflation has started, the patient should be placed in reverse Trendelenburg position with right side up to trap the air embolus in the right atrium. The air can then be retrieved with catheterization aided by transesophageal ultrasound.
 - If a bowel injury goes unrecognized at the time of surgery, it will usually manifest 2 to 3 days postoperatively as a result of thermal injury with abdominal pain, particularly at the port sites, ileus, fever, and leukopenia. The physical examination findings are usually out of proportion to the pain. Causes are usually from cauterizing instruments, but injury can also arise from the heat generated by the camera.
 - Intraoperative urinary cultures should always be obtained in case a postoperative urinary tract infection develops.
 - With regard to urinary leakage, the physical examination typically reveals a tense abdomen with tympanic bowel only on the anterior midline of the abdominal cavity. On abdominal x-ray examination, the bowel is usually centralized and surrounded by a ground-glass appearance, especially in the right and left colonic gutters.
 - Typically, hernias at the port sites require operative intervention on an emergent basis. Port site hernias may manifest as a bulge or tenderness at one of the port sites, but initially can just involve continuous leakage of serous fluid. If findings on physical examination are not definitive, ultrasound can help diagnose a hernia. The size of the trocar does not preclude hernia in children, and port site herniation may occur in 3-mm and 5-mm trocar sites.

we can disseminate the technique and ability to our trainees. This will allow MIS to become part of the mainstream of pediatric urology.

Outcomes for LESS are scant in the literature owing to its infancy in pediatric urology. Koh and colleagues performed LESS nephrectomy in 11 children ranging from infants to adolescents and compared them with a historical cohort with similar perioperative parameters (Koh et al, 2010). The mean operative time, hospital length of stay, and complications were not statistically different between the groups, with preliminary results showing it is a safe and effective modality. Other smaller series have reported similar results (Marietti et al, 2010; Tugcu et al, 2010; Vricella et al, 2010; Ham et al, 2011; Tugcu et al, 2011). Successful completion of LESS pyeloplasty has been reported in one series of 11 patients (Tugcu et al, 2011). Similar surgical parameters and a success rate of 100% were reported. Nonetheless, additional studies are necessary to determine whether a single umbilical incision in children is associated with improved operative outcomes, reduced pain medication requirements, shorter convalescence, and validated measures of postoperative cosmesis.

CONCLUSION

Minimally invasive procedures have revolutionized the way we do surgery in the pediatric urologic patient. The evolution has been through improvement in equipment and teaching technology such as simulation. The outcomes parallel our open surgical results with the benefit of smaller incisions and less manipulation of tissue during the procedures. Compared with conventional laparoscopy, use of robotics has enhanced MIS with increased dexterity, better visualization, and less fatigue, allowing greater precision. We have come a long way in pediatric urologic MIS, but it is still in its infancy.

130 Anomalies of the Upper Urinary Tract

Ellen Shapiro, MD, and Shpetim Telegrafi, MD

Anomalies of Number

Anomalies of Ascent

Anomalies of Form and Fusion

Anomalies of Rotation

Anomalies of Renal Vasculature

Anomalies of the Collecting System

Congenital anomalies of the upper urinary tract comprise a group of abnormalities, ranging from complete absence of the kidney to aberrant location, orientation, and shape of the kidney, as well as aberrations of the collecting system and blood supply. These diverse entities are among the most common malformations in newborns. Advances in molecular genetics have provided the opportunity to hypothesize regarding the complex mechanisms of normal and abnormal development.

ANOMALIES OF NUMBER

Bilateral Renal Agenesis

Of all the anomalies of the upper urinary tract, bilateral renal agenesis (BRA) has the most profound effect on the fetus. Although Wolfstrigel first recognized BRA in 1671, it was not until Potter's extensive description of the constellation of associated defects that the full extent of the syndrome could be easily recognized (Potter, 1946a, 1946b, 1952). Owing to the myriad of complex molecular events that are required for normal renal development, there is probably no single etiology.

Incidence. The incidence of BRA is rare, with only about 500 cases reported in the literature. Potter (1965) estimated that BRA occurs once in 4800 births, whereas Stroup and colleagues (1990) detected an incidence of 3.5 per 100,000. A study in 8500 pregnancies in Poland documented a higher incidence of 0.25% (Forys et al, 2003). Almost 75% of affected individuals are males. Increasing maternal age may be a risk factor (Bianca et al, 2003), but complications of pregnancy or maternal disease do not appear to influence the incidence of BRA (Ruhland et al, 1998). An autosomal recessive inheritance pattern may exist (Dicker et al, 1984), although other investigators have suggested an autosomal dominant trait with variable penetrance (Kovacs et al, 1991; Murugasu et al, 1991; Moerman et al, 1994; Stella, 1998). When siblings and parents of an index child with BRA were screened, 4.5% had unilateral renal agenesis (URA) (Roodhooft et al, 1984) and 3.5% had BRA (McPherson et al, 1987). This is 1000 times higher than in the general population (Stroup et al, 1990). McPherson (2007) evaluated renal anomalies in families of individuals with congenital solitary kidneys including renal agenesis or a very poorly functioning kidney resulting from dysplasia/hypoplasia. The empirical risk of 7% for offspring, 4% for parents, and 2.5% for siblings may be an underestimation, because not all relatives underwent ultrasound screening. The incidence of BRA in offspring of congenital solitary

kidney probands was approximately 1%, which is significantly greater than the risk found in the general population but less than that for families with a history of BRA. Ultrasound screening has been recommended for parents and siblings of infants born with either URA or BRA or dysgenesis (Roodhooft, 1984). McPherson (2007) has recommended prenatal and/or postnatal ultrasound examination when either parent or another first-degree relative has a congenital solitary kidney.

Syndromic Associations. BRA has been detected in higher-than-expected proportions in esophageal atresia (Saing et al, 1998), cryptophthalmos or Fraser syndrome (Fryns et al, 1997), Klinefelter syndrome (Barroeta et al, 2004), and Kallmann syndrome (Colquhoun-Kerr et al, 1999).

Renal Embryology. The intermediate kidney, or mesonephros, develops and then regresses except for the mesonephric tubules (Uetani and Bouchard, 2009; Costantini and Kopan, 2010). In the male, these are the efferent ductules that serve as a link between the gonad and the mesonephric or wolffian duct (WD) structures (the body and tail of the epididymis and vas deferens). In the female, the mesonephric tubules link the ovary through the fimbriated end of the fallopian tube to the reproductive tract. The WD elongates caudally and fuses with the anterior cloaca. The definitive kidney differentiates from the metanephric blastema, which is a specialized region of the intermediate mesoderm termed the *metanephric mesenchyme* (MM).

This process requires the reciprocal induction between the metanephric blastema and the ureteral bud (UB). The metanephric blastema sends signals to the WD to initiate UB formation from its caudal end between 5 and 7 weeks' gestation. The UB evaginates and invades the metanephric blastema and branches repeatedly in a characteristic pattern to form the collecting duct system. The ureteral tips induce nephron differentiation in the adjacent mesenchyme, forming the mature metanephros (Uetani and Bouchard, 2009). The absence of a nephrogenic ridge on the dorsolateral aspect of the coelomic cavity, or the failure of a UB to develop from the WD, will result in renal agenesis. Therefore for BRA to occur, there must be an alteration in normal molecular development or a mutation that causes renal or ureteral maldevelopment on both sides of the midline (see *Molecular Mechanisms of Mammalian Kidney Organogenesis*).

Relationship of the Wolffian Duct to Müllerian Duct Formation. A review of the relationship of the WD to müllerian duct (MD) development is necessary to understand the genitourinary phenotype of individuals with renal anomalies, or more

specifically, renal agenesis (Kobayashi and Behringer, 2003). Gene fate mapping and lineage tracing experiments show that the WD does not contribute cells to the MD, and the MDs are derived from the coelomic epithelium (Guioli et al, 2007; Orvis and Behringer, 2007). A three-phase model of MD development has been proposed (Guioli et al, 2007; Orvis and Behringer, 2007). In the first phase, cells of the coelomic epithelium in the cervical region of the intermediate mesoderm are specified to become MD cells and have been noted to express *Lim1* (Kobayashi et al, 2005; Orvis and Behringer, 2007; Masse et al, 2009) (Fig. 130-1). After the process of specification is complete, the second phase is heralded by *Wnt4* expression from the mesonephros or coelomic epithelium, which induces these cells that are destined to become the MDs to invaginate (Kobayashi et al, 2004, 2005; Orvis and Behringer, 2007). The second phase of MD development is WD independent and ends when the MD extends caudally and contacts the WD (Carroll, 2005; Kobayashi et al, 2005; Orvis and Behringer, 2007). The third phase involves elongation of the MDs posteriorly until they are joined at the urogenital sinus (UGS). This process is WD dependent, requiring the MD epithelium at its posterior end to be in close physical contact with the WD epithelium, whereas the MDs are separated from the coelomic epithelium only by a basement membrane (Orvis and Behringer, 2007). This intimate relationship between the WD and MD is emphasized in experiments that interrupt the formation of the WD at a specific point and show that the MD could not grow beyond that point to complete its formation (Gruenewald, 1941). *Lim1* in the WD is critical for WD maintenance. Loss of *Lim1* in the WD by inactivation leads to WD loss. Because the MD is dependent on the WD in this third phase, the MDs are again incompletely formed (Kobayashi et al, 2005). This third phase is also dependent on the *Pax2* gene; mice mutants for this gene show cellular invagination but no elongation because the WDs have degenerated (Torres et al, 1995; Miyamoto et al, 1997). Studies have also shown that the WD not only acts as a physical guide but also plays a role in MD elongation through paracrine signaling. More specifically, *Wnt9b* is expressed by the WD epithelium, and gene

inactivation results in incomplete formation of the MDs (Carroll et al, 2005). Loss of *Wnt9b* expression did not affect the WD, per se, or the first two phases of MD development, but it did affect the caudal extension and elongation of the MDs, suggesting that WD signaling by *Wnt9b* is one of the critical factors in directing MD formation (Carroll et al, 2005). For a clinical correlation, see **Unilateral Renal Agenesis: Anomalies in the Female**.

Molecular Mechanisms of Mammalian Kidney Organogenesis. Several genes play a critical role in WD development, including *Pax2/8*, *Gata3*, and *Lim1*. Many of the same genes affecting renal development will also affect internal duct development. If there is gene inactivation of *Pax2/8*, *Gata3*, or *Lim1*, there will be no formation of the kidneys (BRA), ureters, or genital tract (Uetani and Bouchard, 2009). Reciprocal epithelial-mesenchymal inductive signaling between the UB epithelium and the MM regulates the pathway for mammalian kidney development (Yu et al, 2004). UB formation and the induction of its branching require glial cell line-derived neurotrophic factor (GDNF), a secreted growth factor expressed in the MM (Michos et al, 2007). The GDNF ligand activates the RET receptor, which is expressed in the WD epithelium and then around the UB tips as branching proceeds. *Eya1* and *Pax2* positively regulate *Gdnf* expression and localization (Michos, 2009). GDNF activation of RET requires the GDNF family receptor $\alpha 1$ (GFR $\alpha 1$) and is essential for induction of UB formation and initiation of outgrowth and branching (Chi et al, 2009). Most genes that are considered essential for UB formation are also regulators of *Gdnf* or *Ret* expression. Studies of murine kidney development show that *Gdnf*^{-/-} mice have renal agenesis, whereas *Ret*^{-/-} mice have renal agenesis or dysplastic kidneys (Pichel et al, 1996; Schuchardi et al, 1996).

Skinner and colleagues (2008) examined the association between abnormal kidney development and mutations of *RET*, *GDNF*, and *GFR $\alpha 1$* in 29 stillborn fetuses with BRA or URA. Mutations in *RET* were found in 7 of 19 fetuses with BRA and in 2 of 10 fetuses with URA. A mutation in *GDNF* was found in 1 fetus with URA who also had mutations in *RET*. No *GFR $\alpha 1$* mutations were observed. These data suggest that congenital renal agenesis results from *RET* mutations that prevent or impede the embryonic development of *RET*-dependent structures.

After the GDNF/GFR $\alpha 1$ complex binds to RET, the *Wnt11* gene is activated in the epithelial tips of the UB and is associated with UB branching (Majumdar et al, 2003). *Wnt11* is a member of the *Wnt* gene family, which is composed of structurally related genes encoding secreted signaling proteins. These proteins are likely involved in several processes, including regulation of cell fate and patterning during embryogenesis. WNT11 signaling is required for the propagation of mesenchymal GDNF signaling, which establishes the autoregulatory epithelial-mesenchymal GDNF/WNT11 feedback-signaling loop that controls the progression of metanephric branching morphogenesis after initiation of UB outgrowth (Majumdar et al, 2003; Michos et al, 2007).

Bone morphogenetic protein-4 (BMP4), a member of the transforming growth factor- α family, is expressed in the periureteral mesenchyme, and is essential for morphogenesis (Miyazaki et al, 2000, 2003; Michos et al, 2007). In wild-type mouse embryos, BMP4 is expressed by the mesenchyme surrounding the WD and UB. Mesenchymal cells that express BMP4 inhibit UB formation, in part by inhibiting *Wnt11* expression. BMP4 migrates to ectopic sites, thereby preventing ectopic UB formation. The BMP4 mesenchymal cells act in a similar fashion during UB branching by inhibiting side branching and permitting stems to lengthen. Mesenchymal cells that are devoid of BMP4 surround the tip, where further branching proceeds. Mice heterozygous for a null mutation in BMP4 (+/-) manifest anomalies, including hypoplastic/dysplastic kidney, hydroureter, ectopic ureter, ureteral duplication, megaureter, ureterovesical junction obstruction, and reflux (Miyazaki et al, 2000, 2003).

Mammalian Kidney Organogenesis: New Advances. Gremlin 1 (GREM1) is an extracellular BMP antagonist that is expressed in the mesonephric mesenchyme and in the MM (Michos et al, 2004) (Fig. 130-2). GREM1 is upregulated in the mesenchyme around the origin of the UB before the initiation of its outgrowth. BMP activity,

Figure 130-1. Model for müllerian duct (MD) development. At E11.75, after a subset of coelomic epithelium cells (green) are specified, they invaginate in the intermediate mesoderm. Then the invaginating cells form the MD (M, pink). Anteriorly the funnel is opened in the abdominal cavity, and caudally the growing tip extends to and contacts the wolffian ducts (WDs; W, blue) at E12.0. A phase of elongation allows the MD to elongate posteriorly in close contact with the WD. As soon as the MD growing tip has deposited cells and elongated caudally, the physical contact between the ducts is lost by the appearance of mesenchymal cells around the MD epithelium. At E13.5, the two MDs reach the urogenital sinus and fuse together. Developmental stages indicated in this figure correspond to mouse stages. (From Masse J, Watrin T, Laurent A, et al. The developing female genital tract: from genetics to epigenetics. *Int J Dev Biol* 2009;53:411–24.)

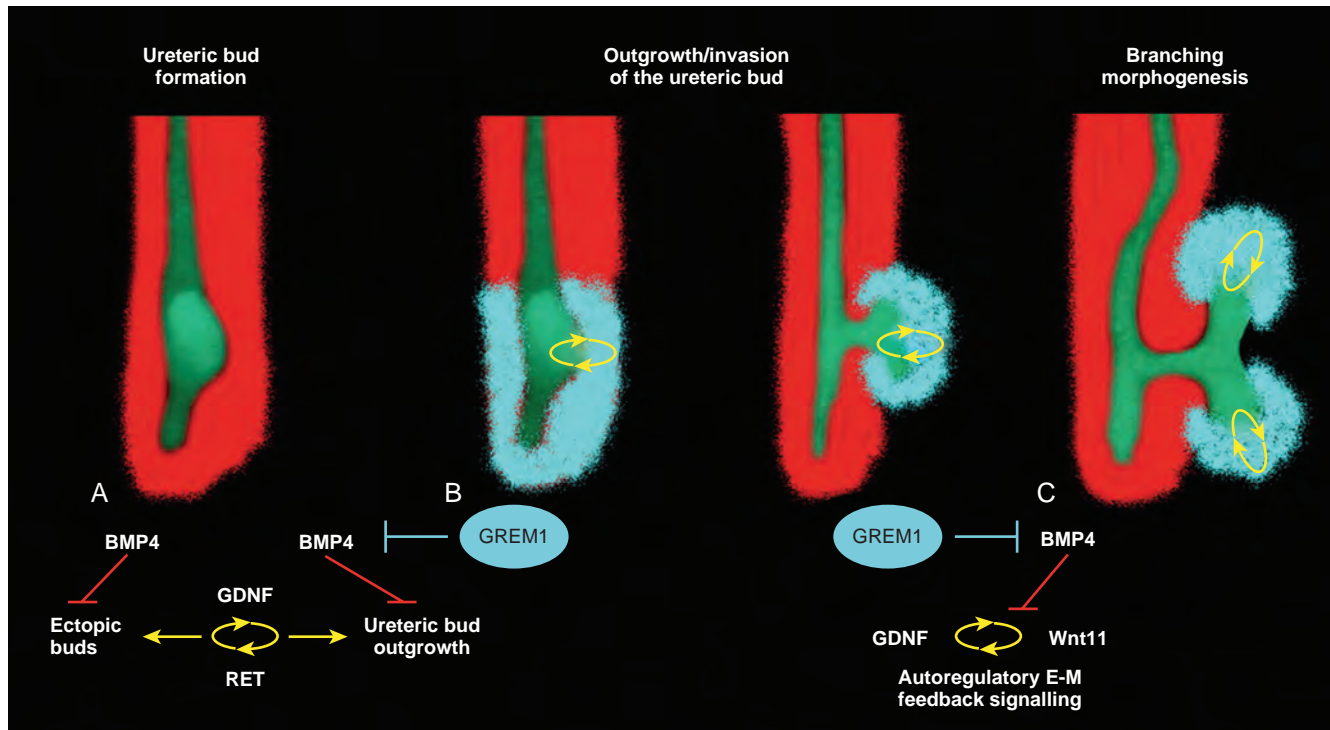

Figure 130-2. Reduction of bone morphogenetic protein-4 (BMP4) activity by gremlin 1 (GREM1) in the mesenchyme around the ureteric bud is essential to enable ureteric epithelial outgrowth, glial cell line–derived neurotrophic factor (GDNF)-RET– and WNT11-mediated epithelial-mesenchymal (E-M) feedback signaling, and branching morphogenesis. **A**, In mouse, the ureteric bud forms in the caudalmost part of the wolffian duct (WD) under the influence of GDNF-RET signaling. During this inductive period, *Bmp4* is expressed by the mesenchyme enveloping the WD. High levels of mesenchymal BMP4 activity inhibit the formation of ectopic epithelial buds and epithelial branching at this stage (prior to E11.0). At this early stage, only low levels of *Grem1* transcripts are detected (not shown). **B**, Expression of the BMP antagonist *Grem1* is upregulated in the mesenchyme around the nascent ureteric bud, thereby locally reducing BMP4 signal transduction (around E11.75-11.0). This reduction of BMP4 activity by GREM1 enables initiation of ureteric bud outgrowth and its invasion into the metanephric mesenchyme. **C**, GREM1 is required to maintain and propagate expression of *Wnt11* in the ureteric epithelial tip(s) and *Gdnf* in the mesenchyme by E-M feedback signaling. (From Michos O, Goncalves A, Lopez-Rios J, et al. Reduction of BMP4 activity by gremlin 1 enables ureteric bud outgrowth and GDNF/WNT11 feedback signaling during kidney branching morphogenesis. *Development* 2007;134:2397–405.)

at this time, is reduced locally. In the *Grem1*-deficient mouse embryo, metanephric development is disrupted at the stage of UB outgrowth initiation, resulting in BRA. This inhibition of UB outgrowth causes progressive loss of *Gdnf* expression, resulting in apoptosis of the MM.

To examine further the relationship of these various ligands and their effects on epithelial-mesenchymal interactions, Michos and colleagues (2007) cultured early *Grem1*-deficient mutant mouse kidney rudiments in a medium supplemented with recombinant GREM1. The addition of GREM1 restored UB outgrowth and induced supernumerary epithelial buds that invaded the MM and initiated branching morphogenesis. At the molecular level, GREM1 replacement activated *Wnt11* expression in the epithelial buds and upregulated *Gdnf* expression in the mesenchyme. Because genetic suppression of BMP4 activity in a *Grem1*-deficient mouse model completely restored kidney development, the local reduction of BMP4 activity by GREM1 was presumed to be critical to the initiation of UB outgrowth and kidney organogenesis.

Because BMP4 signaling by the mesenchyme surrounding the WD prevents the formation of supernumerary epithelial buds, successful initiation of UB outgrowth most likely requires both the antagonism of BMP4 by GREM1 in mesenchyme and the signaling by GDNF from the MM to RET in the ureteric epithelium (Michos

et al, 2007). In addition, autoregulatory feedback signaling between GDNF in the mesenchyme and WNT11 in the epithelial tips regulates branching morphogenesis. *Grem1* is essential for both upregulation of *Wnt11* in the ureteric epithelium and *Gdnf* expression in the mesenchyme and the establishment of epithelial-mesenchymal feedback signaling.

Reviews by Faa and colleagues (2012) and Chai and colleagues (2013) provide further insight into the molecular mechanisms involved in human kidney development. It is well known that the major signaling pathway for ureteral branching is the c-Ret receptor tyrosine kinase whose ligand and downstream target are GDNF and Wnt11, respectively (Faa et al, 2012). Increased Wnt11 expression induces GDNF in adjacent mesenchyme leading to ureteric bud tip cell proliferation, decreased bud tip cell apoptosis, and branching. Investigations examine the role of the renin-angiotensin system (RAS) in known mechanisms regulating UB branching that are essential to normal renal development (Yosypiv, 2014). Gene mutations of the RAS lead to a spectrum of congenital anomalies of the kidney and urinary tract (CAKUT) resulting from defects in UB morphogenesis. UB tips induce surrounding mesenchymal cells to undergo mesenchymal to epithelial transition, forming the glomerulus to the distal tubule. Therefore a decrease in UB branching efficiency will result in a significant decrease in nephron endowment.

Aberrant branching can result in abnormal nephrogenesis and renal hypodysplasia that may progress to chronic renal failure.

In the RAS, renin cleaves angiotensinogen to angiotensin I, which is converted to angiotensin II by the angiotensin-converting enzyme (ACE) (Yosypiv, 2014). Angiotensin II, the primary effector peptide growth factor of the RAS, acts through two major protein receptors: AT₁R and AT₂R. Angiotensin II acts through the AT₂R to stimulate UB branching by upregulating PAX2, a downstream regulator of GDNF that induces the expression of *GDNF/Ret/Wnt11* pathway genes. These genes promote proliferation in UB tip cells and stimulate UB branching. Angiotensin II might also act through the AT₁R to downregulate Spry1, an inhibitor of GDNF/Ret. In turn, this downregulation of Spry1 results in angiotensin II-induced UB branching. The critical role for the RAS in UB morphogenesis is observed when ACE inhibitors or AT₁R antagonists are administered during pregnancy. These inhibitors cause abnormal nephrogenesis, more specifically, renal tubular dysgenesis, which is characterized by absent or underdeveloped proximal tubules. In mice, gene inactivation of angiotensinogen, renin, ACE, or AT₁R results in renal pelvic dilation and hypoplastic papilla. Mutations in the AT₂R gene in mice result in downregulation of the *GNFR/Ret/Wnt11* pathway gene expression, decreased proliferation, and induction of apoptosis of the UB cells. Clinically, ureteral duplication and vesicoureteral reflux are associated with AT₂R gene mutations. These observations in receptor-deficient mice illustrate the need for a critical balance of cell proliferation and cell apoptosis in normal UB branching and nephrogenesis.

SOX genes are an essential component of the c-RET signaling pathway and are important developmental regulators expressed in the tips of the UB that are thought to direct UB branching. Further evidence for the critical role of the c-RET signaling pathway is found in SOX8/9 double mutants because they have abnormal nephrogenesis ranging from renal hypoplasia to renal agenesis (Reginensi et al, 2011).

Gross Pathologic Description of Retroperitoneal Findings

In an extensive autopsy analysis by Ashley and Mostofi (1960), the kidneys were completely absent on gross inspection of the entire retroperitoneum. Complete absence of the renal vessels was observed in about 25% of specimens. Complete ureteral atresia was observed in 39 of the 42 cases of BRA, and partial ureteral absence was noted in three cases. With complete absence of the ureter, a rudimentary kidney was discovered in only a few instances.

The adrenal gland may appear flattened ("lying down" sign) on ultrasonography but is rarely malpositioned or absent (Hoffman et al, 1992). A normally located adrenal gland is expected, because the adrenal cortex develops from primitive mesoderm medial to the urogenital ridge and the medulla develops from ectodermal neural crest cells, whereas the metanephros is derived from the intermediate mesoderm.

Fused and/or horseshoe-shaped glands have been noted on prenatal ultrasound screening (Strouse et al, 2002). Potter (1965) noted that fused glands were often found in the presence of spinal anomalies. In a small number of autopsies, the gonads were absent, indicating the insult occurred before the fifth week and affected the development of the urogenital ridge (Carpentier and Potter, 1959).

KEY POINTS: BILATERAL RENAL AGENESIS

- A total of 40% of the affected infants are stillborn.
- Most of the children who are born alive do not survive beyond 48 hours because of respiratory distress associated with pulmonary hypoplasia.
- The characteristic Potter facies and the presence of oligohydramnios are pathognomonic.
- The ureters are almost always absent, and the bladder is either absent or hypoplastic.
- The adrenal glands are usually positioned normally.
- MD anomalies are commonly observed.

In the Ashley and Mostofi series (1960), about 50% of cases of complete ureteral atresia showed complete absence of the bladder, and in the remainder, a hypoplastic bladder was found consisting only of a muscular tube with a minute lumen. In Potter's series (1965), the bladders were also hypoplastic and lacked ureteral orifices. A normally closed urachus was observed.

Abnormal development of the bladder is thought to be a result of the lack of stimulation by fetal urine production, which starts at 10 to 12 weeks' gestation. Alternatively, it has been postulated that UB and WD structures migrating into the ventral cloacal region are needed to initiate normal bladder development. The absence of the UB, and not the lack of urine, may arrest bladder development (Katz and Chatten, 1974). This theory is supported by the fact that, despite the absence of bladder filling in bladder exstrophy, many of these bladders are functional following surgical closure alone, whereas the bladders associated with bilateral ureteral ectopia (below the bladder neck) almost invariably require augmentation (Jayanthi et al, 1997; Gearhart and Matthews, 2007).

Phenotypic Features. Potter has extensively described phenotypic features associated with BRA. These infants have low birth weights, ranging from 1000 to 2500 g, and intrauterine growth retardation resulting in part from low iron stores in the liver (Georgieff et al, 1996). At birth, oligohydramnios is present. The characteristic facial appearance and deformity of the extremities distinguishes these neonates from normal newborns. The infants look prematurely senile and have "a prominent fold of skin that begins over each eye, swings down in a semicircle over the inner canthus and extends onto the cheek" (Potter, 1946a, 1946b). This facial feature is a sine qua non of nonfunctioning renal parenchyma and suggests that its absence confirms the presence of at least one kidney (Fig. 130-3). The nose is blunted, and a prominent depression exists between the lower lip and chin. The ears appear to be low set, are drawn forward, and are often pressed against the side of the head, making the lobes seem unusually broad and exceedingly large. Periauricular pits and tags have been noted (Wang et al, 2001). The skin can be excessively dry and appears too loose for the body. The hands are relatively large and clawlike. The legs are often bowed and clubbed, with excessive flexion at the hip and knee joints (Das et al, 2002). Occasionally the lower extremities are completely fused as seen with sirenomelia (Liatsikos et al, 1999). A lumbar meningocele with or without the Arnold-Chiari malformation and hydrocephalus is often observed (Ashley and Mostofi, 1960). In Potter's series (1965), anomalies of the gastrointestinal tract were found in 60% of fetuses.

Anomalies of the external genitalia include absence of the scrotum and clitoral hypertrophy. Penile development is usually normal, but in a few cases, penile agenesis or a rudimentary penis and scrotum have been reported (Potter, 1965; O'Connor et al, 1993). Hypospadias is rare and does not appear to be related to the presence or absence of the testes. The testes are undescended in 43% of cases (Carpentier and Potter, 1959). Ashley and Mostofi (1960) found testicular agenesis in 10% of cases. The vas deferens is normal in most cases, implying that the factor responsible for the renal agenesis influenced the UB only after it formed from a completely elongated WD or that the insult affected the induction of the MM.

There is a relatively high incidence of anomalies of the MD structures and ovaries (Carpentier and Potter, 1959). The ovaries are frequently hypoplastic or absent. The uterus is usually rudimentary or bicornuate but occasionally absent. The vagina is a short, blind-ending pouch or is completely absent.

Role of Amniotic Fluid Production and Pulmonary Development. The characteristic facial and limb features may result from deformations rather than malformations of structures as a result of the lack of "cushioning" from amniotic fluid (Thomas and Smith, 1974). This observation was confirmed by an experiment in nature in which one twin with BRA did not have the characteristic Potter facies because it shared the same amniotic sac with the second twin who had an adequate volume of amniotic fluid (Klinger et al, 1997). Fetal renal urine is the major source of amniotic fluid,

Figure 130-3. An anephric child who lived 2 days has the typical Potter facial appearance. **A,** Note the prominent fold and skin crease beneath each eye, blunted nose, and depression between lower lip and chin. **B,** The ears give an impression of being low set because lobes are broad and drawn forward, but actually the ear canals are located normally.

accounting for more than 90% of its volume by the third trimester (Chevalier and Roth, 2007).

Pulmonary hypoplasia and a bell-shaped chest are commonly associated findings that were thought to be caused by uterine wall compression of the thoracic cage as a result of oligohydramnios (Bain and Scott, 1960). Pulmonary airway branching occurs between 12 and 16 weeks' gestation (Reid, 1977). A reduction in the number of branches and a decrease in acini formation in fetuses with BRA imply interference with this process before 16 weeks' gestation (Hislop et al, 1979). They suggested that the anephric fetus fails to produce proline, which is a prerequisite for collagen formation in the bronchiolar tree. The kidney is the primary source of proline (Clemmons, 1977). Thus pulmonary hypoplasia may result from the absence of renal parenchyma and not from diminished amniotic fluid. This hypothesis is supported by the finding of normal lungs in two infants with prolonged leakage of amniotic fluid beginning at a time when pulmonary hypoplasia would have been expected if the amniotic fluid alone was responsible for the defect (Perlman et al, 1976; Cilento et al, 1994).

Peters and colleagues (1991a) proposed a two-step process in pulmonary development, with a primary "renal growth factor" influencing early lung development and an amniotic fluid volume-dependent phase influencing later gestational lung growth. Smith and colleagues (2006) studied early lung development using a murine knockout model of renal agenesis/dysgenesis and anuria. They found that pulmonary development occurred early in embryogenesis, and fetal anuria and hypoplastic lung development preceded oligohydramnios. These observations support the two-step model proposed by Peters (1991a). Alternatively, oligohydramnios resulting from experimentally induced urinary obstruction is associated with pulmonary hypoplasia in fetal sheep that initially showed normal renal function (Peters et al, 1991a, 1991b).

Restoring amniotic fluid volume only partially restores lung growth. Therefore, uropathy-associated pulmonary hypoplasia appears to be a result of oligohydramnios rather than renal dysfunction (Peters, 1991b).

Prenatal and Postnatal Diagnosis. BRA is being diagnosed by prenatal ultrasonography in the second and third trimesters, when severe oligohydramnios is noted and no renal parenchyma can be identified (Forys et al, 2003). Additional diagnostic findings include small lung volumes and chest diameter and abnormal adrenal gland appearance (Heling et al, 2001; Strouse et al, 2002). The characteristic Potter facies and the presence of oligohydramnios are pathognomonic. Amnion nodosum—small, white, keratinized nodules on the surface of the amniotic sac—have been considered a placental hallmark of severe oligohydramnios, but the condition is not pathognomonic and the finding should be interpreted with caution (Adeniran and Stanek, 2007).

In a study of 500 infants, every infant voided within the first 24 hours of life, regardless of the gestational age (Clarke, 1977). After the first 24 hours, anuria without distention of the bladder suggests BRA.

Postnatal Radiographic Evaluation. Renal ultrasonography is the most efficient way to identify the kidneys and bladder and to confirm the presence or absence of urine production. Power Doppler ultrasonography has been highly accurate in determining the status of the renal arteries, even in fetuses with suspected BRA (Sepulveda et al, 1998). A flattened orthotopic adrenal gland supports the diagnosis of an absent kidney (Hoffman et al, 1992). If abdominal ultrasonography is inconclusive, ^{99m}Tc -dimercaptosuccinic acid (^{99m}Tc -DMSA) scanning can be performed. The absence of uptake of the radionuclide in both renal fossae above background activity or in an ectopic location confirms the diagnosis of BRA.

Prognosis. About 40% of the affected neonates are stillborn. Of those neonates born alive, most do not survive beyond the first 24 to 48 hours because of respiratory distress.

Unilateral Renal Agenesis

Complete absence of one kidney occurs more frequently than BRA but is not easily detected on physical examination. The largest study to date of neonates with an isolated single umbilical artery did not find an increased incidence of URA or other malformations (Deshpande et al, 2009). URA may remain undetected unless examination of the external genitalia and/or radiographic evaluation of the female or male pelvis for other reasons shows an anomaly associated with renal agenesis. Since the mid-1990s, prenatal ultrasound examinations have been performed more routinely, and URA is detected with increased frequency (Sipek et al, 1997). A substantial number of cases thought to be URA were a dysplastic or multicystic dysplastic kidney (MCDK) that had involuted before birth (5%) (Hiraoka et al, 2002; Schreuder et al, 2009). MCDK has an incidence of 1 in 4300. Renal aplasia is found in 1 in about 1300 births, which is similar to the incidence of renal agenesis and may be the most common cause of congenital solitary kidney. Renal aplasia includes those units with rudimentary parenchyma and ureter. It is thought to be a result of early regression of the ureteric bud, altered metanephric differentiation, or defects in the branching ureteric duct and the metanephric blastema to “communicate” and to provide reciprocal induction. A plain film of the abdomen supports this diagnosis if the splenic or hepatic flexure of the bowel is in its normal location and not in the ipsilateral renal fossa, suggesting that a dysplastic kidney or MCDK may have formed in the renal fossa before involuting (Matsell, 1998). Curvilinear calcifications on a plain radiograph or computed tomography (CT) scan are another sign of a previous MCDK (Nakano et al, 1996). A flattened adrenal or the spleen (on the left) may be mistaken for a kidney on the 20-week structural ultrasound (Woolf and Hillman, 2006).

Incidence. Most autopsy series suggest that URA occurs once in 1100 births (Doroshov and Abeshouse, 1961). Ultrasound screening of 280,000 school children in Taipei showed the incidence of URA to be 1 in 1200 (Shieh et al, 1990). The high male predominance of BRA is not nearly as striking in the unilateral condition, with a male-to-female ratio of 1.8:1 (Doroshov and Abeshouse, 1961). Absence of a kidney occurs somewhat more frequently on the left side. A familial tendency has been noted (Cascio et al, 1999). McPherson and colleagues (1987) concluded the inheritance of URA was autosomal dominant with a 50% to 90% penetrance. Others who evaluated families with more than one affected individual have confirmed this inheritance pattern (Roodhooft et al, 1984; Battin et al, 1993). For screening recommendations, see *Bilateral Renal Agenesis: Incidence*.

Genetic/Syndromic and Other Associations. An absent kidney has been noted in a number of genetic disorders in which there is a deletion of several chromosomal loci: 8q13.3 (Pierides et al, 2002), 18q22.2 (Dowton et al, 1997), 22q11 (Stewart et al, 1999), as well as in X-linked and sporadic cases of Kallmann syndrome (Quinton et al, 2001). Several syndromes have been associated with URA, including Turner syndrome, Poland syndrome (Mace et al, 1972), Fraser syndrome (Fryns et al, 1997), branchio-oto-renal (BOR) syndrome (Pierides et al, 2002), and DiGeorge anomaly (when associated with maternal insulin-dependent diabetes mellitus) (Wilson et al, 1993; Novak and Robinson, 1994). Maternal diabetes is associated with a threefold increased risk of renal agenesis and dysplasia (Davis et al, 2010). Animal studies have shown that the developing kidney is adversely affected by a high glucose environment, causing dysmorphogenesis of the metanephros and ureteric bud and disruptions in the normal process of nephrogenesis resulting in a reduced population of nephrons (Kanwar et al, 2005; Cunha et al, 2008).

About 30% of children with the VACTERL association (vertebral, imperforate anus, cardiac, tracheo-esophageal atresia, renal, and limb anomalies) have URA (Kolon et al, 2000). Children with

supernumerary nipples (Urbani and Betti, 1996) and disorders of the ears with hearing loss, especially if it is congenital (Huang et al, 2001), and preauricular pits (Pierides et al, 2002) have been thought to have an increased incidence of URA. Studies have not shown a significant relationship between preauricular pits, minor ear tags, and URA (Arora and Pryce, 2004; Deshpande and Watson, 2006). A renal sonogram is recommended when these ear anomalies are found in the presence of other malformations. In addition, when more than one anomaly is present (e.g., ventricular septal defect and an undescended testis) a renal sonogram is prudent, but when specific complexes of anomalies associated with renal agenesis are present (e.g., VACTERL-associated anomalies), a comprehensive radiographic examination of all organ systems including the spine is mandatory.

Embryology. The embryologic basis for URA and BRA is thought to be similar and it is most likely caused by the UB, because increased *RET* mutations occur in humans with renal agenesis (Skinner et al, 2008; Chatterjee et al, 2012; Davis et al, 2014). Complete absence of a bud or aborted ureteral development prevents reciprocal induction, which is critical for the development of the metanephric blastema into the definitive adult kidney. The metanephros is not likely to be responsible for the majority of cases, because the ipsilateral gonad (derived from adjacent mesenchymal tissue) is rarely absent, malpositioned, or nonfunctioning (Ashley and Mostofi, 1960). The high incidence of absent or malformed proximal WD structures in the male and anomalies of the MD structures in the female suggest that the embryologic insult affects the UB primarily in its early development and influences the development of WD derivatives. The abnormality most likely occurs no later than 4 or 5 weeks' gestation, when the UB forms and the WD begins to develop into the ejaculatory duct, seminal vesicle, and vas deferens. The MD in the female begins its medial migration at this time, crossing over the WD (sixth week) during its differentiation into the fallopian tube, uterine horn and body, and proximal vagina (Yoder and Pfister, 1976).

Magee and colleagues (1979) proposed an embryologic classification to explain the association of URA and MD anomalies (Fig. 130-4 on the Expert Consult website). In type I URA, the insult occurs before the fourth week, and there is nondifferentiation of the urogenital ridge structures, including the MD and WD. If unilateral, a uterus consisting of a single MD (unicornate uterus) will form and will be associated with contralateral renal agenesis. In type II URA, the insult occurs early in the fourth week of gestation, affecting both the WD and the UB. Because it is critical that the MD maintains close contact with the WD for MD elongation and subsequent fusion, maldevelopment of the WD affects renal development, MD elongation, contact with the UGS, and subsequent fusion. Therefore a didelphys uterus will form with obstruction of the horn and vagina on the side of the URA (Fig. 130-5). Finally, in type III URA, the insult occurs after the fourth week, and the WD and MD elongation and differentiation proceed normally. In this case, only the UB and metanephric blastema are affected, thereby resulting in isolated URA.

Associated Genitourinary and Adrenal Anomalies. The ipsilateral ureter is absent in about 60% of cases (Ashley and Mostofi, 1960). In this series, 19 of 232 with URA had only a portion of the lower end of the ureter present. In most cases of complete absence of the ureters, the bladder showed no evidence of a ureteric orifice with failure of ipsilateral trigone development (Ashley and Mostofi, 1960). Cell lineage studies using a murine model show that the trigone has a UGS origin and should form normally (Viana et al, 2007; Mendelsohn, 2009). The trigone may not be distinguishable from the surrounding detrusor when the intramural ureter is absent. Therefore the endoscopic appearance of the trigone in this setting has led to the probable misnomer in the case of the “hemitrigone” (in association with complete ureteral agenesis) or “asymmetrical trigone” (in the presence of a partially developed ureter). Except for ectopia or malrotation, anomalies of the contralateral kidney are infrequent (Chow et al, 2005). However, abnormalities of the contralateral ureter are not uncommon, including ureteropelvic and ureterovesical junction obstruction in 11% and 7%, respectively

(Cascio et al, 1999), and reflux in 30% (Atiyeh et al, 1993; Cascio et al, 1999).

Although the ipsilateral adrenal gland may be flattened (Hoffman et al, 1992), adrenal agenesis occurs in fewer than 10% at autopsy (Ashley and Mostofi, 1960) and in 17% of individuals with URA undergoing a CT scan (Kenney et al, 1985) (Fig. 130-6).

Genital anomalies occur much more frequently. The incidence of a reproductive tract malformation for both genders varies from 20% to 40% (Thompson and Lynn, 1966). Despite the predominance of males with URA, reproductive tract abnormalities in females occur in at least 25% to 50% of cases compared with 10% to 15% in males. Regardless of sex, both gonads are usually normal. Therefore the different phenotypes that occur with URA may result from a primary urogenital ridge defect, which explains the finding of gonadal and adrenal agenesis in the minority of cases, or a primary defect in the development of the UB and WD, which leads to the more common cases of URA and frequently observed abnormalities of the WD, MD, and their derivatives.

Anomalies in the Male. The testis and head of the epididymis, which contain the efferent ductules derived from the mesonephric tubules, are invariably present; all structures proximal to

that point, which develop from the WD (the body and tail of the epididymis, vas deferens, seminal vesicle, ampulla, and ejaculatory duct), are absent in almost 50% (Ochsner et al, 1972). Donohue and Fauver (1989) reported 79% of adult males with an absence of the vas deferens have an absent ipsilateral kidney; left-sided lesions predominated with a ratio of 3.5:1. However, bilateral absence of the vas has been noted with URA (McCallum et al, 2001). Occasionally, the WD structures are rudimentary or ectopic rather than absent (Holt and Peterson, 1974). Ipsilateral cryptorchidism rarely occurs. A seminal vesicle cyst caused by obstruction (atresia) of the ejaculatory duct may be seen in association with ipsilateral renal agenesis, and it has been referred to as Zinner syndrome (Pereira et al, 2009). Six cases (5%) were noted among 119 boys found to have URA during ultrasound screening (Shieh et al, 1990). A pelvic sonogram or magnetic resonance imaging (MRI) in boys diagnosed with URA may demonstrate a seminal vesicle cyst (Van den Ouden et al, 1998; Seo et al, 2009) (see Fig. 130-6). In cases of seminal vesicle cysts and URA, the ureter may insert into the prostatic urethra or seminal vesicle. Cystic dysplasia of the rete testis is a rare benign condition, often associated with ipsilateral renal anomalies, most commonly URA, and it has been reported to regress spontaneously and can be

Figure 130-6. Four-year-old boy underwent left inguinal herniorrhaphy. No left vas deferens was present in the spermatic cord. **A**, Postoperative sonogram shows sagittal view of the solitary right kidney with duplicated collecting system. **B**, Sagittal view of the left seminal vesicle cyst (arrow). **C**, Sagittal view of left cystic dysplasia of the rete testis (between calipers). **D**, Sagittal view of an empty right renal fossa with a flattened or “lying down” adrenal gland in a neonate with right renal agenesis (arrowheads).

treated conservatively in the setting of WD defects (Jeyaratnam and Bakalinova, 2010) (see Fig. 130-6).

In males evaluated for infertility, the diagnosis of URA should be suspected when the vas deferens or body and tail of the epididymis are impalpable. In children, URA should be considered when vasal and/or epididymal anomalies are incidentally found at the time of scrotal ultrasonography, herniorrhaphy, or orchiopexy.

Anomalies in the Female. A variety of anomalies may result from incomplete MD formation because of alterations in normal WD development. Approximately one fourth to one third of women with URA have an abnormality relating to WD development (Thompson and Lynn, 1966; Heinonen, 2004). Conversely, 43% of women with genital anomalies have URA (Semmens, 1962; Heinonen, 1997). The most common MD anomalies are a unicornuate uterus with complete absence of the ipsilateral horn and fallopian tube or a bicornuate uterus with rudimentary development of the horn on the affected side (Candiani et al, 1997). The fimbriated end of the fallopian tube, however, is usually fully formed and is analogous to the head of the epididymis in the male (Shumacker, 1938). Partial or complete midline fusion of the MD may result in a double (didelphys) or septate uterus with either a single or a duplicated cervix. Complete duplication or separation of the vagina,

proximal vaginal atresia associated with a small introital dimple, and complete absence of the vagina have been reported (D’Alborton et al, 1981). Obstruction of one side of a duplicated system is not uncommon, and unilateral hematocolpos or hydrocolpos associated with a pelvic mass and/or pain has been described in pubertal girls and has been previously referred to as the Herlyn-Werner-Wunderlich syndrome (Yoder and Pfister, 1976; Tong et al, 2013). Smith and Laufer (2007) suggested the acronym OHVIRA to classify the syndrome of Obstructed Hemivagina and Ipsilateral Renal Anomaly (see Fig. 130-5). In rare instances, this anomalous condition has been mistaken for a large or infected Gartner duct cyst. Sometimes a Gartner duct cyst has been found in a prepubertal girl with an ectopic ureter that is blind ending proximally or one that is connected to a rudimentary kidney (Currarino, 1982). A total of 6% of girls with URA were found to have a Gartner cyst on mass screening of schoolchildren (Shieh et al, 1990). Infertility occurs in as many as 33% of affected women with renal agenesis and unicornuate uterus (Heinonen, 1997). When anomalies of the uterus, including congenital absence of the uterus, unicornuate uterus, and didelphys uterus, are found on ultrasonography or MRI, radiologic investigation of the urinary tract often demonstrates URA or other renal anomalies (Reichman and Laufer, 2010).

Another anomaly often associated with URA is the Mayer-Rokitansky-Küster-Hauser syndrome (MRKH), which is a complex of malformations occurring in 1 of 4500 newborn females (Guerrier et al, 2006; Oppelt et al, 2012; Pizzo et al, 2013). This syndrome includes not only renal anomalies, but also genital tract anomalies ranging from upper vaginal atresia to total müllerian agenesis in an otherwise phenotypically normal 46, XX female. There are two main subtypes. Type I is the typical form characterized by the finding of only symmetrical muscular buds or müllerian remnants and normal fallopian tubes. Type II, which is the more common but considered the atypical form, is characterized by asymmetrical hypoplasia of one or two buds with or without dysplasia of the fallopian tubes. Most importantly, the atypical form is often associated with renal anomalies, primarily URA, ectopia of one or both kidneys, or horseshoe kidney in about 40% to 60% (Guerrier et al, 2006). Duncan and colleagues (1979) reported on the most severe constellation of malformations and referred to this as the MURCS association or müllerian duct aplasia (96%), renal aplasia or ectopia (86%), and cardiothoracic somite dysplasia (two to four anomalous vertebrae between C5-T1 [80%]).

Anomalies of Other Organ Systems. Dursun and colleagues (2005) found that 44% of individuals with a congenital solitary kidney had various nonurologic anomalies including cardiovascular (15%), gastrointestinal (9%), neurologic (3%), and hematologic (6%).

KEY POINTS: UNILATERAL RENAL AGENESIS

- Unilateral agenesis occurs once in 1100 births.
- Males predominate with a ratio of 1.8:1.
- Absence of one kidney occurs somewhat more frequently on the left side.
- The ipsilateral ureter is completely absent in about half of the patients.
- Despite the predominance of males with URA, MD abnormalities occur in 25% to 50% of cases of females with URA compared with WD anomalies in 10% to 15% of males with URA.
- Approximately one fourth to one third of women with MD anomalies are found to have URA.
- Anomalies of other organ systems are found frequently in affected individuals. The more common sites involve the cardiovascular, gastrointestinal, and musculoskeletal systems.

Diagnosis and Radiographic Evaluation. About 90% of fetal kidneys associated with URA or MCDK undergo compensatory hypertrophy in utero from 20 weeks' gestation (Van Vuuren et al, 2012). Postnatally, a retroperitoneal ultrasonogram with color Doppler will show an absence of the kidney and ipsilateral renal vessels. The diagnosis of URA usually can be confirmed with a DMSA scan showing absent uptake of the isotope on one side, with the contralateral kidney often showing compensatory hypertrophy. A DMSA scan will also detect an ectopic (usually pelvic) or a crossed ectopic kidney in cases where the nonvisualized orthotopic kidney is thought to be absent (Volkan, 2003). In some cases, crossed fused ectopia may be difficult to distinguish from a congenital solitary kidney that has undergone compensatory hypertrophy or a solitary complete duplication. A small dysplastic kidney or MCDK may be misdiagnosed as URA when a kidney is not seen on ultrasonography (Mesrobian, 1993).

When a fetus with other suspected organ anomalies undergoes MRI, an absent kidney can be confirmed (Dell'Acqua et al, 2002). When URA is diagnosed especially in infants and young children, a voiding cystourethrogram should be performed, because there is a 28% incidence of contralateral reflux (Kaneyama et al, 2004). **Special Considerations.** The most common question many parents ask is "Will having only one kidney affect my child's

life, and will there be any restrictions on the child's activities?" Psooy (2009) summarizes several North American studies, which suggest that whereas bicycling, sledding, downhill skiing/snowboarding, and equestrian activities are the more common causes of injury, motor vehicle accidents as passenger and pedestrian result in more renal trauma than sports activities. In addition, these sports activities have more than a fivefold relative risk for head injury compared with renal injury. Psooy (2009) notes that children are generally not restricted from these activities just because they have "only one head." Rice and the Council on Sports Medicine and Fitness of the American Academy of Pediatrics (2008) advise that each athlete needs individual assessment for their particular sport and that wearing protective padding may reduce the risk of injury to the solitary kidney, thus allowing participation in most sports. Since those recommendations were proposed, Grinsell and colleagues (2012) used data from the National Athletic Trainers' Association High School Injury Surveillance Study, which calculated the rates for sport-specific injuries to select organs. Although more than 4.4 million athlete-exposures, defined as 1 athlete participating in 1 game or practice, and 23,666 injuries were reviewed, only 18 kidney injuries (3 lacerations and 15 contusions) occurred, none of which were catastrophic or required surgery.

Prognosis. In the past, there was no definitive evidence that having a congenitally solitary kidney predisposed to long-term problems when compared to outcomes of individuals undergoing nephrectomy for Wilms tumor or donor nephrectomy (Shapiro et al, 2003). It is now well recognized that the latter two groups represent completely different conditions compared to the congenitally solitary kidney group in which genetic or environmental events may have altered the development of both kidneys, impacting growth and function throughout life. The remaining kidney is thought to be healthy in living kidney donors who have lower rates of end-stage renal failure (ESRF) than the general population or those undergoing nephrectomy for tumor in childhood (Ibrahim et al, 2009).

Current Concepts Regarding Prognosis in Adults with Unilateral Renal Agenesis. Several studies examine the long-term outcome of children with a solitary functioning kidney (SFK) although there are no definitive conclusions. These studies are based on the "hyperfiltration hypothesis" of Brenner and coworkers (1996). In their rodent model, unilateral nephrectomy led to hyperfiltration of the remnant nephrons and altered sodium balance with subsequent glomerular hypertension. These hemodynamic changes resulted in glomerular damage with albuminuria and glomerulosclerosis. The hyperfiltration hypothesis may be extrapolated to individuals with SFK who have reduced nephron number especially when the solitary kidney is also affected by CAKUT (Westland et al, 2012, 2013b). CAKUT spectrum includes renal agenesis, renal hypo-/dysplasia, MCDK, ureteropelvic junction (UPJ) obstruction, megaureter, posterior urethral valves, and vesicoureteral reflux, and it occurs in 1 in about 600 births (Wiesel et al, 2005) and is found in 20% of those with chromosomal abnormalities (Game et al, 2009). About 10% of those with CAKUT have close relatives with renal abnormalities but most are asymptomatic (Bulum et al, 2013).

There is now evidence that subtle defects in UB branching can cause reduced nephron number, which may lead to renal disease later in life (Brenner and Mackenzie, 1997; Costantini and Shakya, 2006; Chevalier, 2009). In humans, there is an eightfold range in normal variation in the number of glomeruli, that is, from 200,000 to 1.8 million (Hughson, 2003). Therefore it is more likely for an individual with nephron numbers at the lower end of the spectrum to be at greater risk for renal insufficiency at any age and from any etiology. Luyckx and Brenner (2010; Luyckx et al, 2013) propose clinical surrogates for low nephron number and susceptibility to hypertension and renal disease in humans. They include low birth weight, preterm birth, short stature, reduced kidney volume by ultrasonography, low kidney mass by scintigraphy, glomerulomegaly by biopsy, gene polymorphisms (PAX2, RET), and infants of diabetic mothers.

Prenatal renal development may be affected by medications including ACE inhibitors, dexamethasone, antiepileptic medications, and aminoglycosides, as well as intrauterine growth restriction and maternal diabetes. Postnatally, nephrogenesis can affect the premature infant (age ≤ 28 weeks' gestation) when aminoglycosides and nonsteroidal anti-inflammatory agents are administered.

In the past, studies of the renal survival in children with CAKUT have been difficult to perform because they involve decades of follow-up, and the phenotypes of these disorders are not uniform (Pope et al, 1999). Sanna-Cherchi and colleagues (2009) evaluated the long-term functional outcomes in individuals with CAKUT, including those with URA from a single pediatric nephrology center. A total of 312 patients with CAKUT who had a known defect of the number or size of at least one kidney were followed up for as long as 20 years. Patients with isolated vesicoureteral reflux and duplications were excluded. Dialysis-free survival was evaluated, taking into consideration reflux, age at diagnosis, hypertension, proteinuria, and serum creatinine. Six subgroups were examined, including URA, unilateral and bilateral hypodysplasia, posterior urethral valves, MCDK, and horseshoe kidney. These investigators found that by 30 years of age, 19% of all patients were on dialysis, most of whom had posterior urethral valves, bilateral renal hypoplasia, or URA. Further analysis showed that patients with a solitary kidney had a 50% probability of requiring dialysis by 30 years of age. Notably, most of the patients with URA in this study were diagnosed during adolescence and had a normal creatinine level at the time of diagnosis. Interestingly, the patients diagnosed at birth had a slightly elevated creatinine level (0.68 mg/dL). These and other studies point to the fundamental differences in individuals with URA and adults who undergo unilateral nephrectomy. The number of nephrons in children with URA may be abnormally low, and those with fewer nephrons may be at greater risk for developing hypertension, albuminuria, and focal glomerulosclerosis.

The KIMONO (Kidney of Monofunctional Origin) study retrospectively evaluated 116 children with congenital or pSFK (primary solitary functioning kidney, 54 with URA and 62 with MCDK) and 90 children with sSFK (secondary after unilateral nephrectomy for CAKUT or tumor) (Westland et al, 2011). About 30% had ipsilateral CAKUT (the side of the SFK only) in both of these groups. Renal injury was defined as hypertension and/or albuminuria and/or the use of renoprotective medication. Of all children with SFK, 32% had renal injury at a mean age of 9.5 years. GFR declined as early as age 9, and microalbuminuria developed at about age 16. As expected, children with ipsilateral CAKUT, involving pSFK or sSFK, had more renal injury than those in either group without CAKUT. Although the results of the KIMONO study are similar to those of Sanna-Cherchi and colleagues, the study did not consider the different molecular origin(s) and clinical course of the different conditions of each patient. The estimates of renal injury and the proportion of patients who develop ESRF are most likely overestimated because of several factors including selection bias. These studies, however, underscore the importance of identifying those individuals who are more likely to progress to chronic renal failure in adulthood.

Current suggestions for children with SKF include annual assessments of blood pressure and microalbuminuria (first morning specimen) when there is no CAKUT and biannually when there is CAKUT, because hypertension and microalbuminuria (>30 mg/24 hr) are hallmarks of progressive decrease in glomerular filtration rate (Hegde and Coulthard, 2009; Westland et al, 2013a, 2014). Treatment with an ACE inhibitor may be indicated to slow the progression of renal injury (Puddu et al, 2009). Depending on the age of the patient, dietary changes may also be recommended, including limiting salt and avoiding excessive protein intake. Blood pressure, urinary albumin, and serum creatinine are monitored 2 to 4 times a year when the GFR <60 mL/min/1.73 m² or the individual is taking medication for hypertension or proteinuria (Westland et al, 2013a, 2014). In addition, periodic ultrasonography is performed for both pSFK and sSFK especially with CAKUT to assure appropriate compensatory hypertrophy and/

or growth into adolescence. For those with GFR greater than 60 mL/min/1.73 m² who are on no medication, serum creatinine can be performed every 5 years (Westland et al, 2014).

Supernumerary Kidney

The supernumerary kidney is truly an accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchymal mass. Three separate kidneys can form with the third usually being smaller. The two main kidneys are commonly normal and equal in size. The supernumerary kidney may be either totally separate from the normal kidney on the same side or connected to it by loose areolar tissue (Geisinger, 1937). The ipsilateral ureters may be bifid or completely duplicated. The condition is not analogous to a single kidney with ureteral duplication in which the collecting systems drain portions of one parenchymatous mass surrounded by a single capsule.

Incidence. The true incidence of this anomaly cannot be determined because only about 100 cases have been reported (Macpherson, 1987). It affects males and females equally but has a higher predilection for the left side (N'Guessan and Stephens, 1983). Four cases of bilateral supernumerary kidneys have been reported (Oto et al, 2002).

Embryology and Molecular Mechanisms. A second UB or a branching from the initial UB appears as a necessary first step. Next, the nephrogenic anlage may divide into two metanephric tails, which separate entirely when induced to differentiate by the separate or bifid UBs (N'Guessan and Stephens, 1983). The two metanephroi develop only after being penetrated by the bifid or separate UBs.

Kidney development is initiated when a single UB forms from the WD in response to GDNF secreted by the adjacent MM. Posterior restriction of *Gdnf* expression is critical for the development of a UB in the normal position, whereas another intercellular signaling system, including SLIT2 or its receptor ROBO2, is also important in ensuring that a single UB forms in the appropriate location. Grieshammer and colleagues (2004) showed that mutant mice lacking either SLIT2 or its receptor ROBO2 develop supernumerary UBs that are correlated with abnormal maintenance of *Gdnf* expression in anterior MM. The SLIT2/ROBO2 intercellular signaling system restricts, directly or indirectly, the extent of the *Gdnf* expression and plays a critical role in precisely positioning the site of kidney induction.

Description and Associated Anomalies. The supernumerary kidney is a distinct renal mass that may be either completely separate or only loosely attached to the major kidney on the ipsilateral side. In about 60% of cases, it is located caudad to the dominant kidney, which is in its orthotopic position in the renal fossa. When a separate and distinct ureter is present, the supernumerary kidney is more likely to be cranial to the dominant kidney but caudal to the adrenal (Bernik et al, 2001) (Fig. 130-7).

KEY POINTS: SUPERNUMERARY KIDNEY

- The supernumerary kidney is a definitive accessory organ with its own collecting system, blood supply, and distinct encapsulated parenchyma.
- The supernumerary kidney may be either completely separate or loosely attached to the kidney on the ipsilateral side.
- The ureteral interrelationships on the side of the supernumerary kidney can be variable.

The supernumerary kidney is reniform but generally smaller than the main ipsilateral kidney. In almost half of reported cases, the collecting system is severely dilated with thin parenchyma suggesting obstruction. The ipsilateral and contralateral kidneys are usually normal.

The ureteral interrelationships on the side of the supernumerary kidney can be variable. Convergence of the ipsilateral ureters distally to form a common stem and a single ureteral orifice occurs

Figure 130-7. Contrast computed tomography scan showing (A) right and left orthotopic kidneys. B, Right midabdominal malrotated supernumerary kidney.

in 50% of the cases (N'Guessan and Stephens, 1983), which suggests "a bud off of a bud" situation. Two completely independent ureters, each with its own entrance into the bladder, are seen in the other 50% of cases. The Weigert-Meyer principle is usually followed, but in 10% of cases, the caudal kidney has a ureter that does not follow the rule and enters the trigone below the ipsilateral ureter (Tada et al, 1981) (Fig. 130-8 on the Expert Consult website). Individual case reports have described calyceal communications between the supernumerary and the dominant kidney, or fusion of the dominant kidney's ureter with the pelvis of the supernumerary kidney (Kretschmer, 1929) to create a single distal ureter that then enters the bladder (Fig. 130-9 on the Expert Consult website). The vascular supply to the supernumerary kidney is anomalous, depends on its position in relation to the major ipsilateral kidney, and should be separate to be considered a true supernumerary kidney (Kaneoya et al, 1989).

Symptoms. This anomaly is rarely symptomatic but it may become symptomatic in early adulthood. The average age at diagnosis was 36 years. Pain, fever, hypertension, and a palpable abdominal mass are the usual presenting complaints. Urinary infection, obstruction, or both, are the major conditions that lead to evaluation. Ureteral ectopia from the supernumerary kidney may produce urinary incontinence, but this is extremely rare. A palpable abdominal mass secondary to a carcinoma in the supernumerary kidney has been described in two patients. In 25% of all reported cases, the supernumerary kidney is discovered only at autopsy (Carlson, 1950).

Diagnosis. If the supernumerary kidney is normal and asymptomatic, it is usually diagnosed when radiographic studies are performed for other reasons. The kidney may be inferior and distant enough from the ipsilateral kidney so that it does not alter the position of the normal kidney (Conrad and Loes, 1987). If it is in close proximity, it may displace the predominant kidney or its ureter very slightly.

A supernumerary kidney may become symptomatic because of obstruction from a stone (Koureas et al, 2000). In this case, ultrasonography may demonstrate distortion of the normal ipsilateral kidney and ureter. If the collecting system is bifid, the dominant kidney on that side will usually be involved in the same disease process. If the ureters are separate, the ipsilateral kidney may show the effects of an abnormal supernumerary kidney. Magnetic resonance urography (MRU) and retrograde pyelography may be needed to delineate the anomaly. Radionuclide imaging provides information about relative function in the supernumerary and the normal kidneys (Conrad and Loes, 1987). Cystoscopy reveals one or two ureteral orifices on the ipsilateral side, depending on whether the ureters are completely duplicated. Ureteral ectopia may exist in or

outside of the bladder. Occasionally, a supernumerary kidney is not accurately diagnosed until the time of surgery or at autopsy, or it may mimic a duplication (Kaneoya et al, 1989).

ANOMALIES OF ASCENT

Simple Renal Ectopia

When the mature kidney fails to reach its normal location in the "renal" fossa, the condition is known as *renal ectopia*. The term is derived from the Greek words *ek* ("out") and *topos* ("place"), and it literally means "out of place." It is to be differentiated from renal ptosis, in which the kidney initially is located in its proper place (and has normal vascularity) but moves downward in relation to body position. The ectopic kidney has never resided in the appropriate location. An ectopic kidney can be found in one of the following positions: pelvic, iliac, abdominal, thoracic, and contralateral or crossed (Fig. 130-10 on the Expert Consult website).

Incidence. The actual incidence among autopsy series varies from 1 in 500 (Campbell, 1930) to 1 in 1200 (Bell, 1946a), with an average occurrence of about 1 in 900 with no significant difference between the sexes (Abeshouse and Bhisitkul, 1959). Clinically, renal ectopia is more commonly diagnosed in females because they are more apt to undergo urologic evaluation for urinary tract infection (UTI) and/or associated genital anomalies (Thompson and Pace, 1937).

The left side is favored slightly over the right. Pelvic ectopia has been estimated to occur in 1 of 2100 to 3000 autopsies (Stevens, 1937). A solitary ectopic kidney occurs in 1 of 22,000 autopsies (Delson, 1975). By 1973, only 165 cases of a solitary pelvic kidney had been recorded (Downs et al, 1973). Bilateral ectopic kidneys are more rarely observed and account for only 10% of all patients with renal ectopia (Malek et al, 1971) (see Fig. 130-10 on the Expert Consult website).

Embryology. The UB, arising from the WD at the end of the fourth week, grows craniad toward the urogenital ridge, acquiring a cap of metanephric blastema by the fifth week. The developing metanephric tissue and UB migrate cephalad, rotating medially on its long axis. The entire process is completed by 8 weeks' gestation. Factors that may prevent the orderly ascent and rotation of the kidneys include UB maldevelopment (Campbell, 1930), defective metanephric tissue that fails to induce ascent (Ward et al, 1965), genetic abnormalities, and maternal illnesses or teratogenic causes (Malek et al, 1971). A vascular barrier that prevents upward migration secondary to persistence of the fetal blood supply has also been postulated (Baggenstoss, 1951), but the existence of an "early" renal blood supply does not prevent the

Figure 130-8. A to G, Various patterns of urinary drainage of supernumerary and ipsilateral kidneys when ureters are completely separated. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. *J Urol* 1983;130:649–53.)

Figure 130-9. A to H, Various patterns of urinary drainage when ureters form a common stem. All kidney positions are relative only and are depicted on the left side for ease of interpretation. *Dashed lines* indicate that detail was not defined. (From N'Guessan G, Stephens FD. Supernumerary kidney. J Urol 1983;130:649–53.)

Figure 130-10. Incomplete ascent of kidney. The kidney may halt at any level of its ascent from the pelvis. (From Gray SW, Skandalakis JE. The kidney and ureter. In: Gray SW, Skandalakis JE, editors. Embryology for surgeons. Philadelphia: Saunders; 1972.)

affected kidney's movement to its ultimate position. This is probably the result, not the cause, of renal ectopia.

Description and Associated Anomalies. The classification of ectopia is based on the position of the kidney within the retroperitoneum. The pelvic kidney opposite the sacrum and the kidneys below the aortic bifurcation are the most common sites of ectopia; the lumbar kidney resides near the sacral promontory in the iliac fossa and anterior to the iliac vessels, and the abdominal kidney is above the iliac crest and is adjacent to the second lumbar vertebra (see Fig. 130-10 on the Expert Consult website).

The ectopic kidney is usually smaller, and because of fetal lobulations it may not conform to the usual reniform shape. The axis of the kidney is slightly medial or vertical, but it may be tilted as much as 90 degrees laterally so that it lies in a true horizontal plane. The renal pelvis is usually anterior (instead of medial) to the parenchyma, because the kidney has incompletely rotated. As a result, 56% of ectopic kidneys have a hydronephrotic collecting system. Half of these cases are a result of obstruction of the ureteropelvic or the ureterovesical junction (70% and 30%, respectively), 25% from reflux grade III or greater, and 25% from the malrotation alone (Gleason et al, 1994). Reflux has been found in 30% of children with ectopic kidneys (Guarino et al, 2004) (Fig. 130-11).

The length of the ureter usually conforms to the position of the kidney; the ureter is occasionally slightly tortuous but it is rarely redundant. The ureter usually enters the bladder on the ipsilateral side with its orifice positioned normally, except for those unusual cases with ectopic ureters (Borer et al, 1998). The arterial and venous network is anomalous and its vascular pattern depends on the ultimate position of the kidney (Anson and Riba, 1939). There may be one or two main renal arteries arising from the distal aorta or from the aortic bifurcation, with one or more aberrant arteries emanating from the common or external iliac or even the inferior mesenteric artery. The kidney may be supplied entirely by multiple anomalous branches, none of which arise from the aorta. In no instance has the main renal artery arisen from the level of the aorta that would be its proper origin if the kidney were positioned normally.

Although the contralateral kidney is usually normal, it is associated with a number of congenital defects. Malek and colleagues (1971) and Thompson and Pace (1937) reported the incidence of contralateral agenesis to be high (Chow et al, 2005). Bilateral ectopia occurs infrequently (10%) (see Fig. 130-11).

KEY POINTS: SIMPLE RENAL ECTOPIA

- The left side is affected slightly more than the right.
- Pelvic ectopia has been estimated to occur in 1 of 2100 to 3000 autopsies.
- Fifty-six percent of ectopic kidneys have a hydronephrotic collecting system. Half of these cases result from obstruction at the ureteropelvic or the ureterovesical junction (70% and 30%, respectively), 25% from reflux grade III or greater, and 25% from the malrotation alone.
- Vesicoureteral reflux has been found in 30% of children with ectopic kidneys.
- The incidence of genital anomalies in the patient with ectopia is about 15%.
- Most ectopic kidneys are clinically asymptomatic, except in cases of associated ectopic ureter.

The most striking feature of renal ectopia is the association of genital anomalies. The incidence varies from 15% (Thompson and Pace, 1937) to 45% (Downs et al, 1973). Twenty percent to 66% of females have one or more of the following abnormalities of the reproductive organs: bicornuate or unicornuate uterus with atresia of one horn (McCrea, 1942), rudimentary or absent uterus and proximal and/or distal vagina (D'Alborton et al, 1981), and duplication of the vagina. Among male patients, 10% to 20% have a recognizable associated genital defect; undescended testes, duplication of the urethra, and hypospadias are the most common

(Thompson and Pace, 1937). Fourteen percent of patients with a cloacal malformation have an ectopic kidney (Dursun et al, 2005).

Rarely is the adrenal gland absent or abnormally positioned. A total of 21% of individuals exhibit anomalies of other organ systems (Downs et al, 1973); most involve the skeletal or cardiac systems.

Diagnosis. With the increasing use of various imaging modalities, the incidence of ectopic kidneys is increasing although most ectopic kidneys are asymptomatic. Vague abdominal complaints or ureteral colic secondary to an obstructing stone are the most frequent symptoms leading to the diagnosis of an ectopic kidney. The abnormal position of the kidney results in a pattern of direct and referred pain that is atypical for colic and may be misdiagnosed as acute appendicitis or as pelvic inflammatory disease in female patients. Symptoms rarely occur because of organs that are adjacent to the ectopic kidney. Renal ectopia may also present with a UTI or a palpable abdominal mass. Seven cases of concomitant renal and ureteral ectopia presenting with urinary incontinence have been reported (Borer et al, 1998). Diagnosis may be difficult because of the diminished function of some ectopic kidneys. The kidneys may be very small and/or dysplastic with essentially no function, leading to the misdiagnosis of URA. Both DMSA scanning and/or MRU may be necessary to diagnose these unusual cases (Borer et al, 1998).

The diagnosis of an ectopic lumbar or pelvic kidney is made when the renal sonogram fails to show a kidney in its orthotopic location and when power color Doppler delineates the main renal artery and intrarenal vasculature of the ectopic kidney.

Cystoscopy, when performed, will demonstrate ureteral orifices that are invariably normal unless the ureteral orifice is also ectopic. If surgery is indicated on an ectopic kidney, MR arteriography may be useful preoperatively to define the anatomy of the renal vasculature, especially in cases of solitary ectopia.

Prognosis. The ectopic kidney is no more susceptible to disease than the orthotopic kidney, except for the development of hydronephrosis or stones (Gleason et al, 1994; Benchekroun et al, 2002). This may be a result of the anteriorly placed pelvis and malrotation of the kidney, which may impair drainage of urine from a high insertion of the ureter to the pelvis or anomalous vasculature that partially obstructs one of the major calyces or the upper ureter. In addition, there may be an increased risk of injury from blunt abdominal trauma, because the low-lying kidney is not protected by the rib cage.

Van den Bosch and colleagues (2010) examined the urologic and nephrologic consequences of both simple and crossed renal ectopia. They found no adverse effects on blood pressure or kidney function during childhood. They did note that although global renal function of these kidneys was normal, the relative function of the ectopic kidney on DMSA scan was 38%.

Anderson and Harrison (1965), in a review of pregnant women with renal ectopia, found no increased occurrence of maternal or fetal complications related to the ectopic kidney (Anderson and Harrison, 1965; Delson, 1975). Dystocia from a pelvic kidney is rare but may require cesarean section. Although three cases of cancer in an ectopic kidney have been reported, there is no increased risk for malignancy. Before modern imaging, in at least five instances solitary ectopic kidneys were mistaken for pelvic malignancies and were removed (Downs et al, 1973).

Cephalad Renal Ectopia

The kidney may be positioned more craniad than normal when there is an omphalocele (Pinckney et al, 1978). When the liver herniates into the omphalocele with the intestines, the kidneys continue to ascend until the diaphragm arrests their ascent. Both kidneys are ectopic and are positioned immediately beneath the diaphragm at the level of the 10th thoracic vertebra. The ureters were excessive in length but were otherwise normal. A color Doppler sonogram or MR arteriography demonstrates that the origin of each renal artery is more cephalad than normal. Patients usually have no symptoms caused by malposition, and urinary drainage is not impaired.

Thoracic Kidney

Intrathoracic ectopia denotes either a partial or a complete protrusion of the kidney above the level of the diaphragm into the posterior mediastinum (Fig. 130-12). It is the rarest form of renal ectopia; fewer than 5% of patients with ectopia have an intrathoracic kidney, with an incidence of 1:13,000 at autopsy (Campbell, 1930).

Incidence. At least 200 patients with a thoracic kidney have been reported (Lacasta Garcia et al, 1999), four of whom had bilateral thoracic kidneys (Liddell et al, 1989). There appears to be a slight left-sided predominance of 1.5:1, and the sex ratio favors males by 2:1 (Lozano and Rodriguez, 1975). This entity has been found on prenatal ultrasonography (Masturzo et al, 2001) and in all age groups, but it is most commonly detected in adults undergoing chest radiography for other reasons (Drop et al, 2003) (see Fig. 130-12).

Embryology. The kidney reaches its final location by the end of 8 weeks' gestation. At this time, the diaphragmatic leaflets are formed as the pleuroperitoneal membrane separates the pleural from the peritoneal cavity. Mesenchymal tissues associated with this membrane eventually form the muscular component of the diaphragm. It is uncertain whether delayed closure of the diaphragmatic anlage allows for protracted renal ascent above the level of the future diaphragm or whether the kidney overshoots its usual position because of accelerated ascent before normal diaphragmatic closure (N'Guessan and Stephens, 1984). Delayed involution of mesonephric tissue has been proposed as a causative factor (Angulo et al, 1992), because intrathoracic kidneys occur in only 0.25% of patients with a diaphragmatic hernia (Donat and Donat, 1988). Renal angiography has demonstrated either a normal site (Lundius, 1975) or a more cranial origin (Franciskovic and Martincic, 1959) of the renal artery from the aorta supplying the thoracic kidney (see Fig. 130-12).

Description. The kidney is situated in the posterior mediastinum and usually has completed the normal rotation process. The renal contour and collecting system are normal. The kidney usually lies in the posterolateral aspect of the diaphragm in the foramen of Bochdalek. At this point, the diaphragm thins out and a flimsy membrane surrounds the protruding portion of kidney. Therefore the kidney is not within the pleural space (N'Guessan and Stephens, 1984). The lower lobe of the adjacent lung may be hypoplastic secondary to compression by the kidney mass. The renal vasculature and the ureter enter and exit from the pleural cavity through the foramen of Bochdalek.

Associated Anomalies. The ureter is elongated to accommodate the excessive distance to the bladder. N'Guessan and Stephens (1984) determined that the adrenal gland typically occupies its normal location and the contralateral kidney is usually normal. No consistent anomalies have been described in other organ systems.

Symptoms. The vast majority of affected individuals are asymptomatic. Flank pain was the presenting symptom in a case of UPJ obstruction in a thoracic kidney (Hampton and Borden, 2002). The case depicted in Figure 130-12 shows severe hydronephrosis of a previously normal thoracic kidney, presumably caused by intermittent obstruction by the muscular fibers of the diaphragm (Shapiro, personal communication, 2000).

Diagnosis. The diagnosis is commonly made after a routine chest radiograph shows the affected hemidiaphragm slightly elevated. A smooth, rounded mass is seen extending into the chest near the midline on an anteroposterior film and along the posterior aspect of the diaphragmatic leaflet on a lateral view (see Fig. 130-12). A thoracic kidney may be found at the time of thoracotomy for a suspected mediastinal tumor (DeNoronha et al, 1974). CT or MRU is currently the imaging modality of choice.

Prognosis. Neither autopsy series nor clinical reports suggest that a thoracic kidney will usually cause serious urinary or pulmonary complications.

ANOMALIES OF FORM AND FUSION

Crossed Renal Ectopia with and without Fusion

When a kidney is located on the side opposite that in which its ureter inserts into the bladder, the condition is known as *crossed ectopia*. Ninety percent of crossed ectopic kidneys are fused to their ipsilateral mate. Except for horseshoe kidney, they account for the majority of fusion defects. Fusion anomalies are usually diagnosed in children as part of a constellation of malformations, in young adults during evaluation for delayed menarche, and in the elderly as incidental findings (Glodny et al, 2008).

Fusion anomalies of the kidney were categorized as crossed ectopia with fusion, crossed ectopia without fusion, solitary crossed ectopia, and bilaterally crossed ectopia (McDonald and McClellan, 1957) (Fig. 130-13). The fusion anomalies have been designated as (1) unilateral fused kidney with inferior ectopia; (2) sigmoid, or S-shaped; (3) lump or cake; (4) L-shaped, or tandem; (5) disc, shield, or doughnut; and (6) unilateral fused kidneys with superior ectopia (Fig. 130-14 on the Expert Consult website).

Incidence. Abeshouse and Bhisitkul (1959) reported almost 500 cases of crossed ectopia with and without fusion that presented primarily with clinical symptoms. Glodny and colleagues (2008) reported on 24 crossed fused ectopia found on a CT scan performed for nonurologic indications.

Sixty-two patients with crossed ectopia without fusion have been reported (Winram and Ward-McQuaid, 1959). This represents approximately 10% of all crossed ectopic kidneys (Lee, 1949). The anomaly occurs more commonly in males with a ratio of 2:1, and left-to-right ectopia is seen three times more frequently than right-to-left ectopia (Lee, 1949).

Solitary crossed ectopia has been reported in 34 patients (Miles et al, 1985; Gu and Alton, 1991). Males predominate with a ratio of 2:1. The crossed ectopia involves migration of the left kidney to the right side with absence of the right kidney, rather than the reverse, with a ratio of almost 2:1 (Takei et al, 1976). In most cases, the kidney fails to ascend and rotate completely. The left-to-right crossed kidney is rarely a MCDK. Bilateral crossed renal ectopia has been described in five patients (Abeshouse and Bhisitkul, 1959) and is considered the rarest form. Abeshouse and Bhisitkul (1959) compiled 443 reports of crossed ectopia with fusion and estimated its occurrence at 1 in 1000 live births. This figure varies with the type of fusion anomaly; the **unilaterally fused kidney with inferior ectopia is the most common variety**, whereas fusion with superior ectopia is the least common. The autopsy incidence has been

Figure 130-12. One-year-old girl with febrile urinary tract infection. **A**, Intravenous pyelogram shows a right thoracic kidney (arrow) and left orthotopic kidney. She was found to have bilateral vesicoureteral reflux and underwent bilateral ureteral reimplants. At age 16, she developed right back pain and chest tightness. **B**, Chest radiograph demonstrates right diaphragmatic eventration and a right intrathoracic kidney (arrow). **C**, Magnetic resonance urogram shows coronal T1 fat saturation after contrast images of poorly functioning right hydronephrotic kidney located superior to the liver and inferior to the right lung with absence of the posterior right hemidiaphragm, permitting the colon to enter the right hemithorax. **D**, Angiographic sequence demonstrating right renal artery (arrow) arising from the aorta at the normal level of the left renal artery coursing superiorly to enter the right renal hilum. **E**, Intraoperative right retrograde pyelogram shows narrowing at the ureteropelvic junction. Figure 130-13. A to D, Four types of crossed renal ectopia.

calculated at 1 in 2000 (Baggenstoss, 1951). There is a slight male predominance (3:2), and a left-to-right crossover occurs somewhat more frequently than its counterpart.

Embryology. The UB enters the metanephric blastema adjacent to the anlage of the lumbosacral spine. During the next 4 weeks, the developing kidney is at the level of the L1-L3 vertebrae. Because the mechanisms responsible for complete ascent of the kidney are unknown, the cause of crossed ectopia is also unknown.

Cook and Stephens (1977) postulated that crossover is the result of malalignment and abnormal rotation of the caudal end of the developing fetus, with the distal curled end of the vertebral column being displaced to one side or the other. As a result, either the cloaca and WD structures lie to one side of the vertebral column, allowing one ureter to cross the midline and enter the opposite nephrogenic blastema, or the kidney and ureter are transplanted to the opposite side of the midline during "normal" renal ascent (Hertz et al, 1977; Maizels and Stephens, 1979).

Kelalis and colleagues (1973) implicated teratogenic factors after they noted an increased incidence of associated genitourinary and other organ system anomalies. Finally, genetic influences may play a role, because familial inheritance of crossed renal ectopia has been reported (Rinat et al, 2001).

Fusion of the metanephric masses may occur when the renal anlagen are still in the true pelvis before or at the start of cephalad migration, or it may occur during the latter stages of ascent. The extent of fusion is determined by the proximity of the developing renal anlagen to one another. After fusion, midline retroperitoneal structures, the aortic bifurcation, the inferior mesenteric artery, and the base of the small bowel mesentery impede the advancement of the kidneys toward their normal location (Joly, 1940).

Description. Fusion of a crossed ectopic kidney is related to the time it comes in contact with its mate. The crossed kidney usually lies caudad to its normal counterpart on that side. It is likely that migration of each kidney begins simultaneously, but ascent of the ectopic renal unit lags behind because of crossover time. Therefore it is the superior pole of the ectopic kidney that usually joins with the inferior aspect of the normal kidney. Ascent continues either until the uncrossed kidney reaches its normal location or until one of the retroperitoneal structures prevents further migration of the fused mass. The final shape of the fused kidneys depends on the time and extent of fusion and the degree of renal rotation that has occurred. No further rotation is likely after the two kidneys have joined. An anteriorly placed pelvis suggests early fusion, whereas a medially positioned renal pelvis indicates that fusion probably occurred after rotation was completed.

Ninety percent of crossed ectopic kidneys are fused with their mate. When they are not fused, the uncrossed kidney usually resides in its normal dorsolumbar location with proper orientation, whereas the ectopic kidney is inferior and is in either a diagonal or a horizontal position with an anteriorly placed renal pelvis. A variable distance usually separates the two kidneys, and its own capsule

of Gerota fascia surrounds each. In every case of crossed ectopia without fusion, the ureter from the normal kidney enters the bladder on the same side, and that of the ectopic kidney crosses the midline at the pelvic brim and enters the bladder on the contralateral side (Fig. 130-15).

In cases of solitary crossed ectopia, the kidney is usually located somewhat low but in the opposite renal fossa at the level of L1-L3 and is oriented anteriorly, having incompletely rotated on its vertical axis (Purpon, 1963). When the kidney remains in the pelvis or ascends only to the lower lumbar region, it may assume a horizontal lie with an anteriorly placed pelvis because it has failed to rotate fully (Trabisky and Bhisitkul, 1965). The ureter crosses the midline above the S2 vertebra and enters the bladder on the opposite side (Gu and Alton, 1991). The contralateral ureter, if present, is often rudimentary (Caine, 1956). Bilateral crossed ectopia may have normal-appearing kidneys and renal pelves, but the ureters cross the midline at the level of the lower lumbar vertebrae (Abeshouse and Bhisitkul, 1959).

KEY POINTS: CROSSED RENAL ECTOPIA WITH AND WITHOUT FUSION

- When a kidney is located on the side opposite that in which its ureter inserts into the bladder, the condition is known as crossed ectopia.
- Ninety percent of crossed ectopic kidneys are fused with their mate; the superior pole of the ectopic kidney usually joins with the inferior aspect of the normal kidney.
- In all the types of fusion anomalies, the ureter from each kidney is usually orthotopic.
- The highest incidence of associated anomalies occurs in children with solitary renal ectopia and involves both the skeletal system and genital organs.

Inferior Ectopic Kidney. Two thirds of all unilaterally fused kidneys involve inferior ectopia. Both renal pelves are anterior, so fusion probably occurs relatively early.

Sigmoid, or S-Shaped, Kidney. The sigmoid, or S-shaped, kidney is the second most common anomaly of fusion. The crossed kidney is inferior, with the two kidneys fused at their adjacent poles. Fusion of the two kidneys occurs relatively late, after complete rotation on the vertical axis has occurred. Therefore each renal pelvis is oriented correctly, and they face in directions opposite from one another. The lower convex border of one kidney is directly opposite the outer border of its counterpart, creating an S-shaped appearance to the entire renal outline. The ureter from the normal kidney courses downward anterior to the outer border of the inferior kidney, and

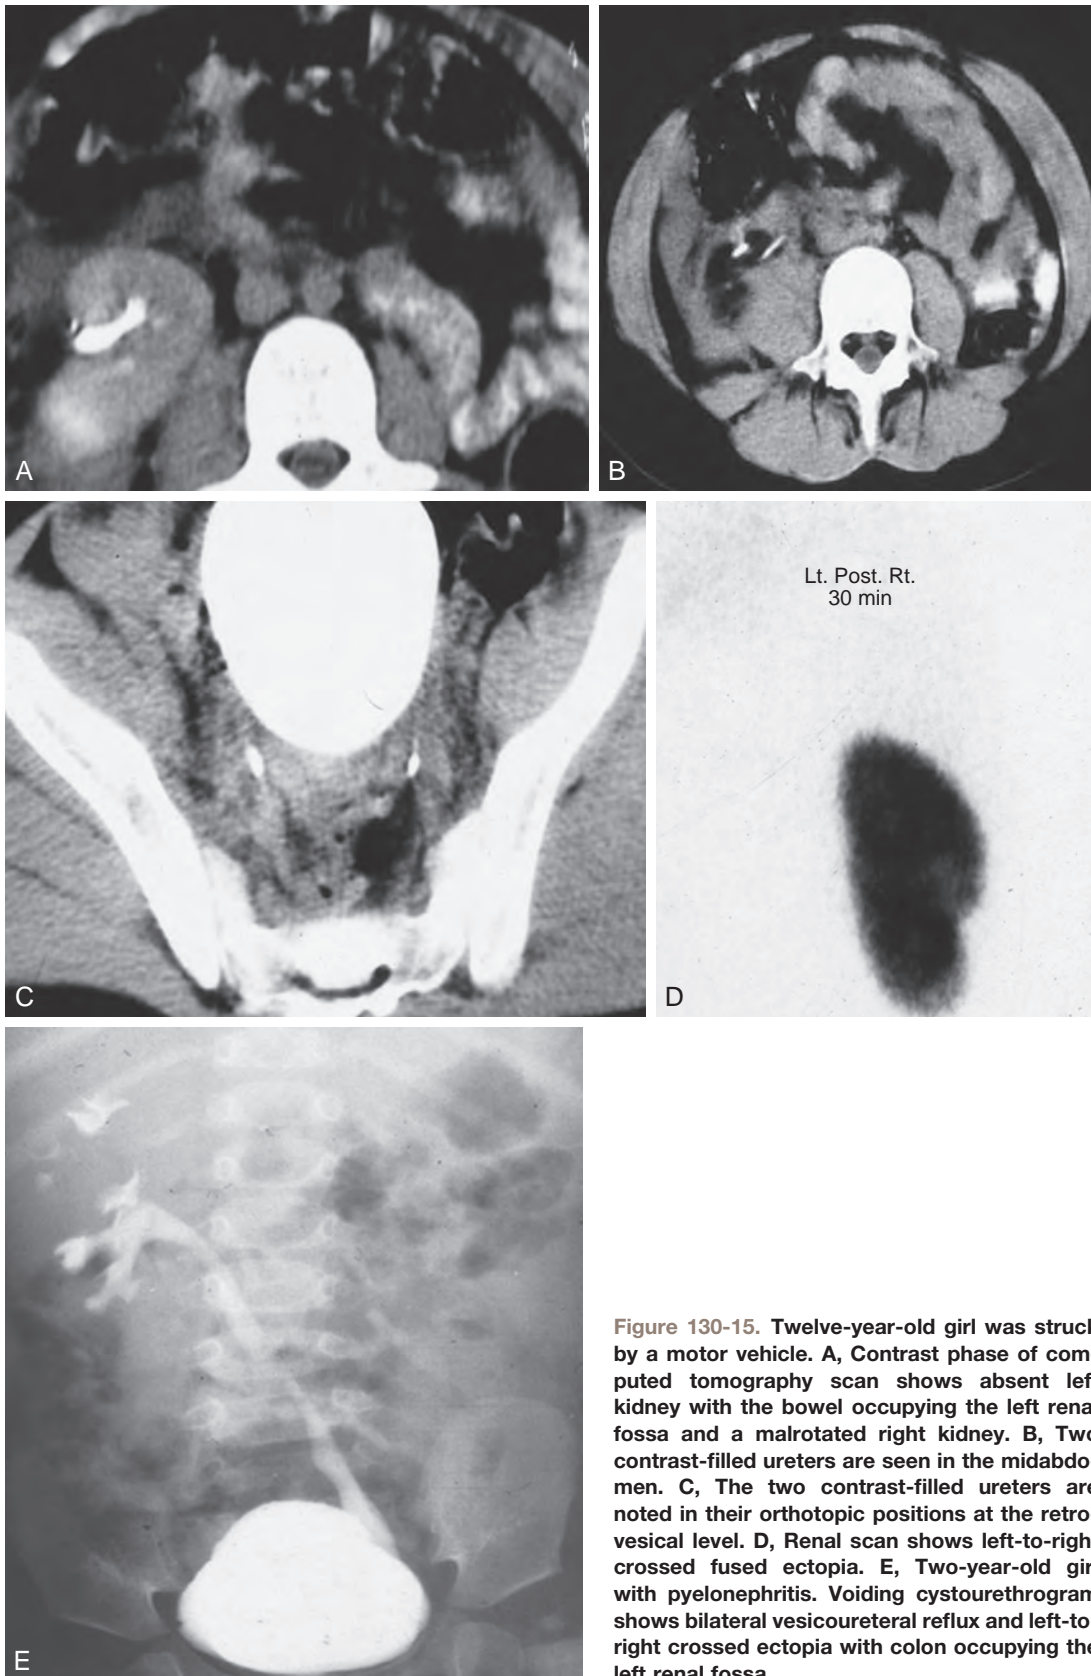

Figure 130-15. Twelve-year-old girl was struck by a motor vehicle. A, Contrast phase of computed tomography scan shows absent left kidney with the bowel occupying the left renal fossa and a malrotated right kidney. B, Two contrast-filled ureters are seen in the midabdomen. C, The two contrast-filled ureters are noted in their orthotopic positions at the retrovesical level. D, Renal scan shows left-to-right crossed fused ectopia. E, Two-year-old girl with pyelonephritis. Voiding cystourethrogram shows bilateral vesicoureteral reflux and left-to-right crossed ectopia with colon occupying the left renal fossa.

the ectopic kidney's ureter crosses the midline before entering the bladder.

Cake or Lump Kidney. The cake or lump kidney is a relatively rare form of fusion (Fig. 130-16). Extensive fusion has occurred over a wide margin of maturing renal anlage, resulting in one mass. The

total kidney is irregular and lobulated. Ascent usually progresses only as far as the sacral promontory, but in many instances the kidney remains within the true pelvis. Both renal pelvises are anterior, and they drain separate areas of parenchyma. The ureters do not cross. Only ten cases of pelvic cake kidney drained by a single ureter

Figure 130-16. A, Lump or cake kidney showing the unusual anatomy, with the anterior blood supply coming from above and the ureters leaving from below. B, Sonogram of cake kidney in sagittal view (arrows). (A, Courtesy Dr. H. S. Altman.)

have been reported (Schwartz, 2010) with one case associated with a unicornuate uterus, and another associated with bilateral absence of the vas.

L-Shaped Kidney. The L-shaped, or tandem, kidney occurs when the crossed kidney assumes a transverse position at the time of its attachment to the inferior pole of the normal kidney. The crossed kidney lies in the midline or in the contralateral paramedian space anterior to the L4 vertebra. Rotation about the long axis of the kidney produces an inverted or a reversed pelvic position. The ureter from each kidney enters the bladder on its respective side.

Disc Kidney. Disc, shield, doughnut, or pancake kidneys are kidneys that have joined at the medial borders of each pole to produce a doughnut- or ring-shaped mass. More extensive fusion along the entire medial aspect of the kidneys creates a disc or shield shape. The lateral aspect of each kidney retains its normal contour. This type of fusion differs from the lump or cake kidney in that the reniform shape is better preserved owing to a less extensive degree of fusion (see Fig. 130-16). The pelves are anteriorly placed, and the ureters remain uncrossed. The collecting system drains each respective half of the kidney and does not communicate with the opposite side.

Superior Ectopic Kidney. The least common variety of renal fusion is the crossed ectopic kidney that lies superior to the normal kidney. The lower pole of the crossed kidney is fused to the upper pole of the normal kidney. The renal units retain a fetal orientation, with both pelves lying anteriorly, suggesting that fusion occurred very early.

Regardless of the type of fusion encountered, the vascular supply to the kidneys is variable. The crossed ectopic kidney is supplied by one or more branches from the aorta or common iliac artery (Rubinstein et al, 1976). The normal kidney frequently has an anomalous blood supply, with multiple renal arteries originating from various levels along the aorta. The solitary crossed ectopic kidney generally receives its blood supply from the aorta or iliac artery on the side where it is positioned (Tanenbaum et al, 1970).

Associated Anomalies. In all the types of fusion anomalies, the ureteral orifice associated with each kidney is usually orthotopic. Except for solitary crossed ectopia, most patients with crossed ectopia have a normal trigone (Yates-Bell and Packham, 1972). The incidence of an ectopic ureteral orifice from the crossed renal unit is about 3% (Abeshouse and Bhisitkul, 1959; Hendren et al, 1976). The ureter from the uncrossed renal segment of a fusion anomaly occasionally has an ectopic orifice or an associated ureterocele (Malek and Utz, 1970; Hendren et al, 1976). Vesicoureteral reflux is noted in 20% of crossed ectopia and in 71% of bilateral crossed ectopia (Kelalis et al, 1973; Guarino et al, 2004) (see Fig. 130-15).

Currarino and Weisbruch (1989) reported 10 cases of midline renal fusion in which a single ureter divided into two pelves that stretched across the midline to drain one respective half of the total parenchymatous mass. In 4 of the 10 cases, a second ureter was present that drained a separate duplex system on either the right or left side. Most of the affected individuals had an imperforate anus, an abnormal vertebrae, or both.

The ectopic kidney may have associated UPJ obstruction (29%), reflux (15%), or carcinoma (Abeshouse and Bhisitkul, 1959; Gleason et al, 1994). Only five tumors have been reported, all of which were renal cell carcinomas and one was in a solitary crossed ectopic kidney (Stimac et al, 2004; Grotas and Phillips, 2009).

The highest incidence of associated anomalies occurs in children with solitary renal ectopia and involves both the skeletal system and genital organs (Gleason et al, 1994). This may be related more to renal agenesis than to the ectopic anomaly, per se. Fifty percent and 40% of solitary crossed renal ectopia have a skeletal or genital abnormality, respectively (Gu and Alton, 1991). The most common genital anomalies are cryptorchidism or absence of the vas deferens and vaginal atresia or a unilateral uterine abnormality (Takei et al, 1976). Imperforate anus has also been observed in 20% of those with solitary crossed ectopia.

In general, the occurrence of an associated nonurologic anomaly in crossed renal ectopia, excluding solitary crossed ectopia, is low; the most frequent are imperforate anus (4%), orthopedic anomalies (4%), skeletal abnormalities, and cardiovascular septal defects.

Symptoms. Most individuals with crossed ectopic anomalies present no symptoms. These anomalies are often discovered incidentally at autopsy, during routine perinatal ultrasound, or after bone scanning. When symptoms occur, they usually develop in the third or fourth decades of life and they include vague lower abdominal pain, pyuria, hematuria, and UTI (Gleason et al, 1994). It is believed that the abnormal kidney position and the anomalous blood supply may impede drainage from the collecting system, creating a predisposition to UTI and calculus formation (Collura et al, 2004). Romans and colleagues (1976) observed that when a stone in a crossed ureter causes colic, the pain is lateralized to the anephric side or the side of the embryonic origin of the ureter, whereas when there is pyelonephritis or obstruction at the UPJ in the crossed kidney, the lumbar pain is on the side of the kidneys. These observations suggest ureteral, not renal, migration as a causative factor in crossed ectopia.

An asymptomatic abdominal mass is the presenting sign in one third of cases (Abeshouse and Bhisitkul, 1959; Nussbaum et al, 1987). Hypertension evaluation shows an ectopic fusion anomaly (Abeshouse and Bhisitkul, 1959).

Diagnosis. Ultrasonography and DMSA scanning have currently shown more asymptomatic cases (Volkan et al, 2003). Multidetector three-dimensional (3D) CT urography is excellent for delineating the renal parenchyma, collecting system, ureters, and vascular supply of the fused kidneys. The main limitation of this modality is the increased risk of significant radiation exposure, which is especially problematic for children, pregnant women, and individuals requiring repeat examinations (Türkvtan et al, 2009). MRU and magnetic resonance arteriography (MRA) should be performed in children undergoing extensive surgery on an ectopic kidney. Cystoscopy and retrograde pyelography can be useful in mapping the collecting system and pattern of drainage.

Prognosis. Most individuals with crossed renal ectopia have normal longevity. However, those with an obstructive-appearing collecting system are at risk for the development of UTI, renal calculi, or both (Kron and Meranze, 1949).

Horseshoe Kidney

The horseshoe kidney is the most common of all renal fusion anomalies. The anomaly consists of two distinct renal masses lying vertically on either side of the midline and connected at their respective lower poles by a parenchymatous or fibrous isthmus that crosses the midplane of the body (Natsis et al, 2014).

Incidence. Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 persons (Campbell, 1970). A review of more than 15,000 radiologic imaging studies showed an incidence of 1 in 666 individuals (Weizer et al, 2003). Horseshoe kidney is found more commonly in males with a ratio slightly greater than 2:1 (Weizer et al, 2003). The abnormality has been discovered in all age groups. In autopsy series, it is more prevalent in children (Segura et al, 1972). This early-age prevalence is related to the high incidence of multiple congenital anomalies associated with the horseshoe kidney, some of which are incompatible with long-term survival (Scott, 2002). Horseshoe kidneys have been reported in identical twins (Bridge, 1960) and among several siblings (David, 1974). It is doubtful that this anomaly represents a particular genetic predisposition, but it may be the result of a genetic expression with a low degree of penetrance (Leiter, 1972).

Embryology. The abnormality occurs between 4 and 6 weeks' gestation, after the UB has entered the renal blastema. In view of the ultimate spatial configuration of the horseshoe kidney, the entrance of the UB occurred before rotation and before renal ascent (Fig. 130-17).

Tripathi and colleagues (2010) investigated the role of axial structures, including the notochord and the floor plate of the neural tube in metanephric kidney development. The notochord, which is replaced by the vertebral column in higher vertebrates, is essential for the formation of the floor plate. In addition, the sonic hedgehog (*Shh*) gene exists in these structures and is thought to affect renal development. Using a murine model, these investigators disrupted the notochord and neural plate, which resulted in kidney fusions. Then they only inactivated *Shh* in the notochord and floor plate, which also resulted in kidney fusion. These findings suggest that the notochord is *not* necessary for nephrogenesis but is *required* for correct positioning of the metanephric kidney, whereas the axial SHH signal is critical for kidney positioning along the mediolateral axis. These studies provide insights into the molecular basis for horseshoe kidney formation and provide an explanation for the increased incidence of horseshoe kidneys in children with vertebral and neural tube defects (see [Associated Anomalies](#)).

Description. In 95% of cases, the kidneys join at the lower pole, which occurs before the kidneys have rotated on their long axes. The pelves and ureters of the horseshoe kidney are usually anteriorly placed, crossing ventrally to the isthmus (see Fig. 130-17). Very rarely, the pelves are anteromedial, suggesting that fusion occurred after some rotation occurred. In a small subset, an isthmus connects both upper poles (Love and Wasserman, 1975). In addition, migration is usually incomplete and it is thought that the inferior mesenteric artery prevents full ascent.

The isthmus is generally bulky and consists of parenchymatous tissue with its own blood supply (Glenn, 1959; Love and Wasserman, 1975). Occasionally it is just a flimsy midline structure composed of fibrous tissue that tends to draw the renal masses close together. The isthmus is located adjacent to the L3 or L4 vertebra just below the origin of the inferior mesenteric artery from the aorta. The isthmus most often lies anterior to the aorta and vena cava, but it has been reported to pass between the inferior vena cava and the aorta or even behind both great vessels (Dajani, 1966). In some instances, the anomalous kidneys are very low, anterior to the sacral promontory or even in the true pelvis behind the bladder (Campbell, 1970). Fused pelvic kidneys are observed in the *Foxd1* mouse mutant, which show defects in UB branching and nephron formation (Levinson et al, 2005).

The calyces are normal in number and are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane (on a line drawn from the lower to the upper poles). The lowermost calyces extend caudally or even medially to drain the isthmus and may overlies the vertebral column (Strauss et al, 2000).

The ureter may insert high on the renal pelvis and lie laterally, probably as the result of incomplete renal rotation. It courses downward and has a characteristic bend as it crosses over and anterior to the isthmus (Strauss et al, 2000). The lower ureter enters the bladder normally and rarely is ectopic.

The blood supply to the horseshoe kidney can be variable. In 30% of cases it consists of one renal artery to each kidney (Glenn, 1959) (see Fig. 130-17). Duplicate or triplicate renal arteries may supply one or both kidneys. The blood supply to the isthmus and lower poles is also variable. The isthmus and adjacent parenchymal masses might receive a branch from each main renal artery, or they may have their own arterial supply from the aorta originating either above or below the level of the isthmus. Not infrequently, branches from the inferior mesenteric, common or external iliac, or sacral arteries supply this area (Kolln et al, 1972).

Associated Anomalies. About 30% of horseshoe kidneys are associated with other congenital anomalies (Boatman and colleagues (1972). The autopsy incidence of other anomalies is greater in children who die at birth or in early infancy than in those who reach adulthood (Scott, 2002). This implies that a horseshoe kidney occurs more often in association with other serious congenital anomalies. The organ systems most commonly affected include the skeletal, cardiovascular (primarily ventriculoseptal defects [Voisin et al, 1988]), and central nervous system. Horseshoe kidney is found in 3% of children with neural tube defects (Whitaker and Hunt, 1987). Anorectal malformations are frequently encountered in these patients. Horseshoe kidney is seen in 60% of females with Turner syndrome (Lippe et al, 1988).

KEY POINTS: HORSESHOE KIDNEY

- Horseshoe kidney occurs in 0.25% of the population, or about 1 in 400 persons.
- The isthmus is bulky and consists of parenchymatous tissue.
- The calyces, normal in number, are atypical in orientation. Because the kidney fails to rotate, the calyces point posteriorly, and the axis of each pelvis remains in the vertical or obliquely lateral plane.
- The blood supply can be variable.
- Horseshoe kidney is frequently found in association with other congenital anomalies.
- UPJ obstruction, causing significant hydronephrosis, occurs in as many as one third of individuals with horseshoe kidneys.
- Sixty percent of patients with horseshoe kidneys remained asymptomatic for an average of 10 years after discovery.

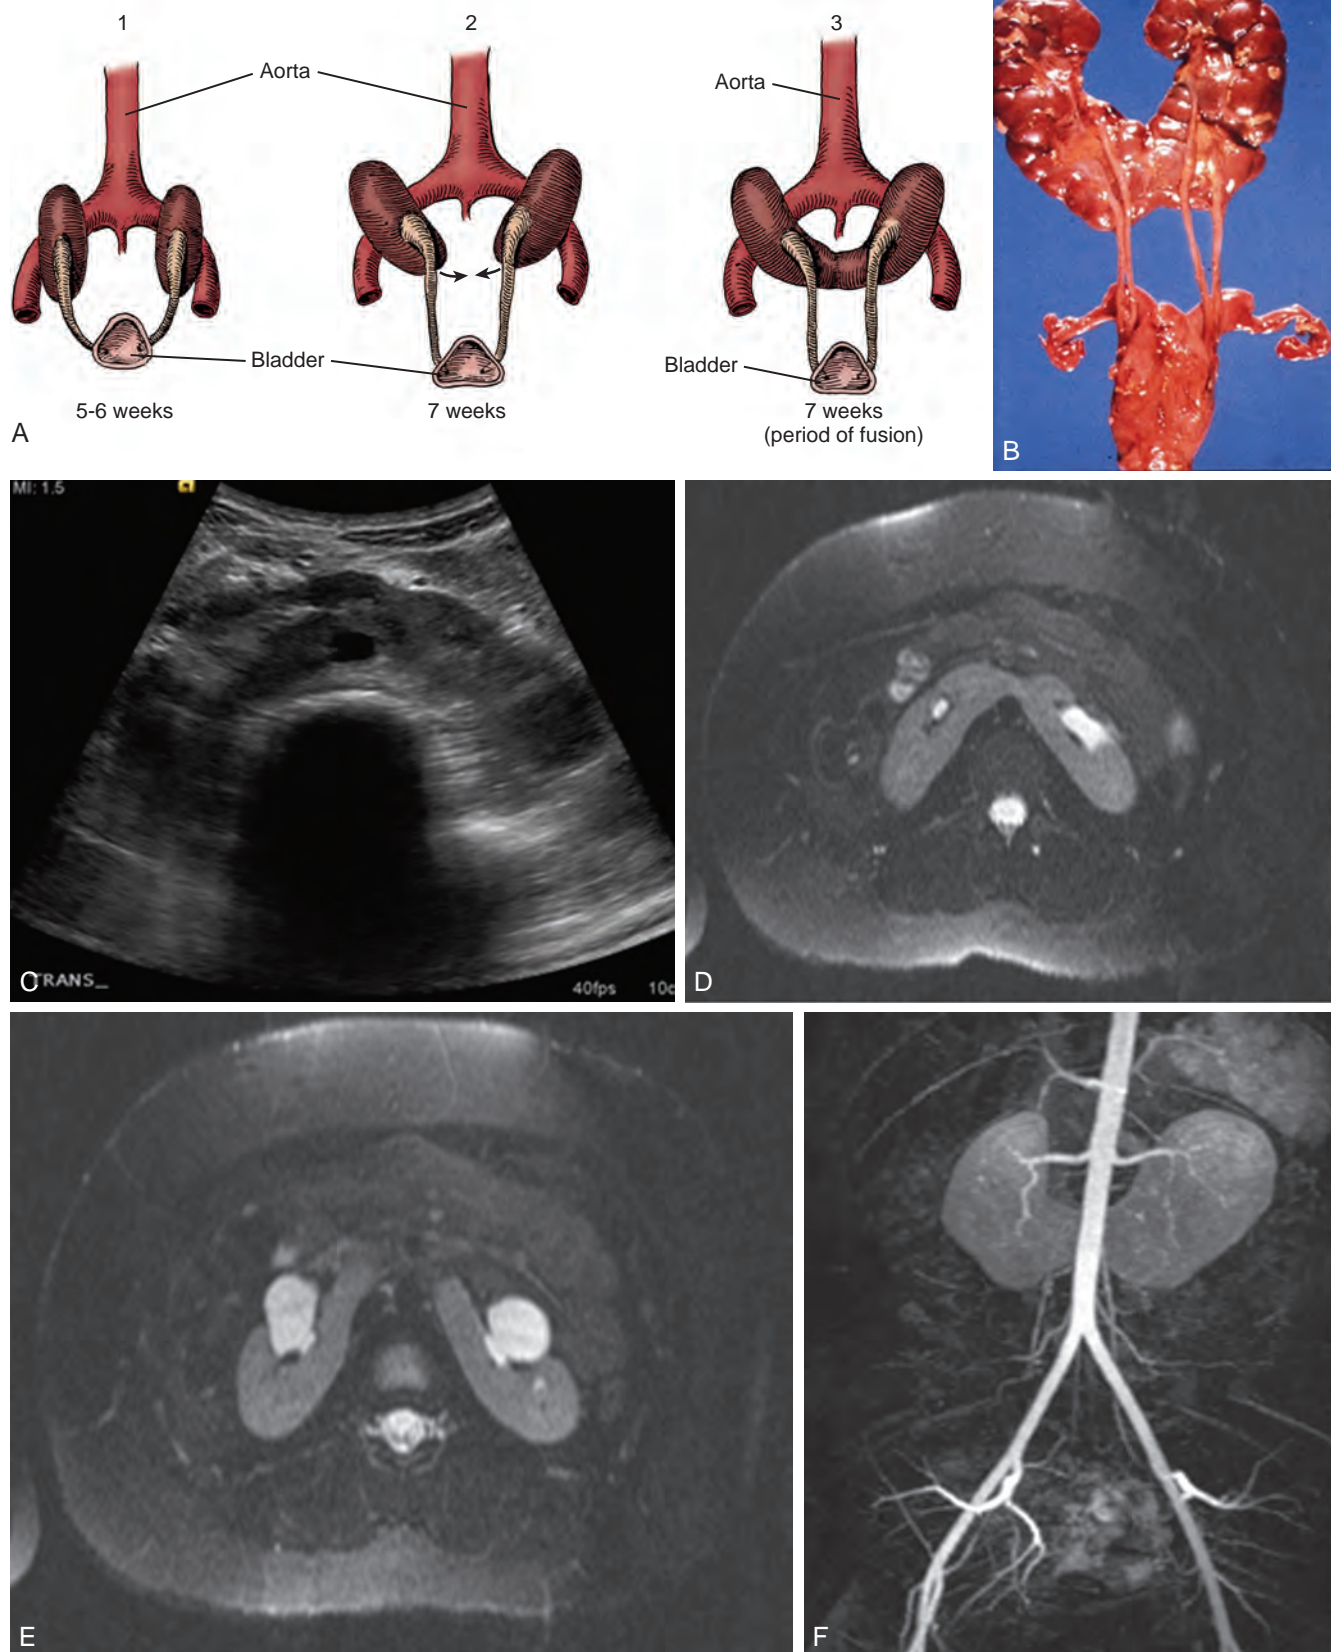

Figure 130-17. A, Embryogenesis of horseshoe kidney. The lower poles of the two kidneys touch and fuse as they cross the iliac arteries. Ascent is stopped when the fused kidneys reach the junction of the aorta and the inferior mesenteric artery. B, Postmortem specimen showing horseshoe kidney with bilateral duplicated ureters. C, Sonogram of horseshoe kidney at the level of the isthmus. D, Magnetic resonance (MR) urogram shows axial T2 fat-saturated image at the level of the isthmus. E, Axial T2 fat-saturated image demonstrates extrarenal pelves. F, Angiographic sequence shows variable blood supply to the kidney.

Figure 130-17, cont'd G, Transverse sonogram of 14-year-old girl with left flank pain found to have marked left hydronephrosis in a horseshoe kidney (*arrow*). H, MAG3 scan demonstrates left ureteropelvic junction obstruction. I, Coronal T2 images of MR urogram show the isthmus (*arrow*) and severe left hydronephrosis. (A, From Benjamin JA, Schullian DM. Observation on fused kidneys with horseshoe configuration: the contribution of Leonardo Botallo [1564]. *J Hist Med Allied Sci* 1950;5:315–26, after Gutierrez, 1931; B, from Weiss, MA, Mills, SE. *Atlas of genitourinary tract disorders*. Philadelphia: JB Lippincott; 1988.)

Boatman and his colleagues (1972) also discovered an increased occurrence of other genitourinary anomalies associated with a horseshoe kidney. Hypospadias and undescended testes occurred in 4% of males, and a bicornuate uterus, a septate vagina, or both, were noted in 7% of the females.

Duplication of the ureter occurs in 10% of cases (Boatman et al, 1972); in some cases this has been associated with an ectopic ureterocele (see Fig. 130-17). Vesicoureteral reflux has been noted in more than half (Cascio et al, 2002). Previously, up to one third with horseshoe kidney had hydronephrosis thought to be secondary to UPJ obstruction (Whitehouse, 1975; Das and Amar, 1984) (see Fig. 130-17). The high insertion of the ureter into the renal pelvis, its abnormal course anterior to the isthmus, and the anomalous blood supply to the kidney may individually or collectively contribute to

the hydronephrosis. In the modern era, horseshoe kidneys are frequently discovered incidentally, and their apparent hydronephrosis more often shows a nonobstructed pattern on radionuclide scanning.

Horseshoe kidneys are also incidentally observed on ^{99m}Tc bone scan as a result of renal uptake and excretion of the isotope (O'Brien et al, 2008). Back pain that prompts a bone scan may have resulted from UPJ obstruction (Shapiro, personal communication, 2013).

Cystic disease, including multicystic dysplasia in one half (the upper pole) of one side (Boullier et al, 1992) and the lower pole of one side (Shapiro, personal communication, 2004), and adult polycystic kidney disease have been reported with horseshoe kidney (Correa and Paton, 1976). DMSA scanning in 22 patients showed asymmetrical function in 63% (Kao et al, 2003). Stone formation

has been commonly seen in horseshoe kidney. Metabolic stone evaluation in 11 of 37 of these stone formers showed at least one abnormality, with an average of 2.68 abnormalities per 24-hour urine collection. Hypovolemia, hypercalciuria, and hypocitraturia were the most common metabolic defects (Raj et al, 2004).

Symptoms. At least 50% with horseshoe kidneys are asymptomatic, and in most instances the anomaly is an incidental finding at autopsy (Kolln et al, 1972; Pitts and Muecke, 1975). Symptoms are typically related to hydronephrosis, infection, or calculus formation. The most common symptom is vague abdominal pain that may radiate to the lower lumbar region. UTIs occur in 30% of patients, and calculi have been noted in 20% to 80% (Glenn, 1959; Kolln et al, 1972; Pitts and Muecke, 1975; Evans and Resnick, 1981; Sharma and Bapna, 1986; Benckekroun et al, 1998). Five percent to 10% of horseshoe kidneys are confirmed after palpation of an abdominal mass (Kolln et al, 1972).

Diagnosis and Radiographic Appearance. The classic radiologic features on a plain film of the abdomen include kidneys that are somewhat low lying and close to the vertebral column and that have a vertical or outward axis with the lower poles being more medial than in the normal kidney (O'Brien et al, 2008). The kidneys may be observed by the delineation of the perinephric fat. Prenatal ultrasonography detects most horseshoe kidneys (Sherer and Woods, 1992; Van Every, 1992). Postnatal ultrasonography detects the isthmus joining the two lower poles of the kidneys in the midline, unless the isthmus is only a thin fibrous band. Ultrasound diagnosis is made by scanning horizontally along the midline in a craniocaudal direction, especially in children and in thin patients. Radionuclide scanning demonstrates the abnormal axis of a horseshoe kidney. A continuous band across the midline is observed if the isthmus contains functioning parenchyma. CT and MRU can also be used to characterize the isthmus. MRA will delineate the vascular anatomy for preoperative planning (O'Brien et al, 2008).

Prognosis. Although Smith and Orkin (1945) believed that horseshoe kidneys are almost always associated with disease, Glenn (1959) observed patients with horseshoe kidneys for an average of 10 years after discovery and found that almost 60% of these remained asymptomatic. Only 13% had persistent urinary infection or pain, and 17% developed recurrent calculi.

Many disease processes have been described with a horseshoe kidney, but this likely reflects the relative frequency of the congenital defect. Kidney cancers have been reported in about 150 individuals with horseshoe kidney (Stimac et al, 2004). Renal cell carcinoma accounts for about half of these cases, although the incidence is no greater than that in the general population. Two cases of bilateral tumors have been reported (Romics et al, 2002). Renal pelvic tumors and Wilms tumor each accounted for about 25% of the total, with sarcoma and carcinoids occurring much less frequently. Overall, 41 of 8617 (0.48%) Wilms tumors in the National Wilms Tumor study occurred in horseshoe kidneys, primarily on the left side, rarely in the isthmus, and practically all with favorable histology (Neville et al, 2002). The incidence of Wilms tumor in horseshoe kidneys is 1.76 to 7.93 times higher than that expected in the general population (Mesrobian et al, 1985). Thirty-seven percent of these Wilms tumors were initially inoperable. However, with preoperative chemotherapy, most patients were salvaged, yielding a 75% preservation rate of renal parenchyma (Neville et al, 2002). Wilms tumor may originate in the isthmus (Beck and Hlivko, 1960), creating a bizarre radiologic picture (Walker, personal communication, 1977). Except for renal pelvic tumors, a surprisingly high number of renal cancers arise in the isthmus (Blackard and Mellinger, 1968). For this reason, it has been suggested that teratogenic factors are responsible for abnormal migration of nephrogenic cells to form an isthmus, which then leads to the horseshoe shape and the predisposition for the development of cancer in this portion of the kidney (Hohenfellner et al, 1992).

It has been suggested that the increased occurrence of chronic infection, obstruction, and stone formation explains the higher-than-expected incidence of renal pelvic tumors because the incidence exceeds that of the general population (Dische and Johnston,

1979). Survival from these tumors is related to the pathology and stage of the tumor at diagnosis and not to the renal anomaly (Murphy and Zincke, 1982). Surveillance for tumors in symptomatic horseshoe kidneys may be prudent.

Because a horseshoe kidney is located above the pelvic inlet, it should not adversely affect pregnancy or delivery (Bell, 1946b). The development of renal failure associated with adult polycystic kidney disease is not any greater in a horseshoe kidney (Correa and Paton, 1976). A worldwide review of horseshoe kidney transplant from the Netherlands noted that 23 whole and 57 split horseshoe kidneys have been transplanted with initial failure rates of only 4.3% and 13.4% for en bloc and for split transplants, respectively. An overall 80% graft survival rate has been reported at 5 years (Stroosma et al, 2001).

ANOMALIES OF ROTATION

The kidney, as it assumes its final position in the "renal" fossa, orients itself so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as *malrotation* and is often described in conjunction with other renal anomalies, such as ectopia with or without fusion or horseshoe kidney. This discussion centers on malrotation as an isolated renal entity.

Incidence. Campbell (1963) found renal malrotation in 1 of 939 autopsies, and Smith and Orkin (1945) noted 1 case per 390 hospital admissions. It is frequently observed in association with Turner syndrome (Gray and Skandalakis, 1972b). Males are affected twice as often as females, but there does not appear to be any predilection for side.

Embryology. It is thought that medial rotation of the collecting system occurs simultaneously with renal migration. The kidney starts to turn during the sixth week, just when it is leaving the true pelvis, and it completes this process by rotating 90 degrees toward the midline by the time ascent is complete at the end of 9 weeks' gestation.

In 1912, Felix postulated that rotation is actually the result of unequal branching of successive orders of the budding ureteral tree, with two branches extending ventrally and one dorsally during each generation or division. Each ureteral branch then induces differentiation of the metanephrogenic tissue. More parenchyma develops ventrally than dorsally, and the pelvis seems to rotate medially. Weyrauch (1939) accepted this theory of renal rotation as the result of excessive ventral versus dorsal branching of the ureteral tree and concluded that the fault of malrotation lies entirely with the ureter. A late-appearing UB may insert into an atypical portion of the renal blastema, leading to a lessened propensity for the developing nephric tissue to shift. Late appearance of the UB is almost always associated with an aberrant origin from the WD; this translates into ureteral ectopia at the level of the lower urinary tract. Mackie and colleagues (1975), however, did not describe any malrotation anomalies in their study of renal ectopia. The renal blood supply does not appear to be the cause nor does it appear to be a limiting factor in malrotation, but rather it follows the course of renal hyporotation, hyper-rotation, or reverse rotation.

KEY POINTS: ANOMALIES OF ROTATION

- The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent so that the calyces point laterally and the pelvis faces medially. When this alignment is not exact, the condition is known as malrotation.
- Malrotation is frequently associated with Turner syndrome.

Description. The kidney and renal pelvis normally rotate 90 degrees ventromedially during ascent. Weyrauch (1939), in a detailed study, categorized the various abnormal phases of medial and reverse rotation according to the position of the renal pelvis (Fig. 130-18 on the Expert Consult website).

Figure 130-18. Rotation of the kidney during its ascent from the pelvis. The left kidney with its renal artery and the aorta are viewed in transverse section to show normal and abnormal rotation during its ascent to the adult site. A, Primitive embryonic position; hilus faces ventrad (anterior). B, Normal adult position; hilus faces mediad. C, Incomplete rotation. D, Hyper-rotation; hilus faces dorsad (posterior). E, Hyper-rotation; hilus faces laterad. F, Reverse rotation; hilus faces laterad. (From Gray SW, Skandalakis JE. *Embryology for surgeons*. Philadelphia: Saunders; 1972.)

Figure 130-19. Sonogram showing (A) sagittal view of malrotated right kidney. B, Transverse view of malrotated right kidney. Note the anterior position of the renal pelvis (arrows).

Ventral Position. The pelvis is ventral and in the same anteroposterior plane as the calyces, which point dorsally because they have undergone no rotation at all. This is the most common form of malrotation (Fig. 130-19).

Ventromedial Position. The pelvis faces ventromedially because of an incompletely rotated kidney. Excursion probably stops during the seventh week of gestation when the kidney and pelvis normally reach this position. The calyces thus point dorsolaterally.

Dorsal Position. Renal excursion of 180 degrees occurs to produce this rarest position. The pelvis is dorsal to the parenchyma, and the vessels pass behind the kidney to reach the hilum.

Lateral Position. When the kidney and pelvis rotate between 180 degrees to 360 degrees, or when reverse rotation of up to 180 degrees occurs, the pelvis faces laterally and the kidney parenchyma resides medially. The renal vascular supply provides the only clue to the actual direction of excursion. Vessels that course ventral to the kidney to enter a laterally or dorsolaterally placed hilum suggest reverse rotation, whereas a path dorsal to the kidney implies excessive ventral rotation.

In cases of isolated malrotation, other characteristic features may be present. The kidney shape may be discoid, elongated, oval, or triangular, with flattened anterior and posterior surfaces. Fetal lobulations are invariably present and are accentuated beyond normal limits. A dense amount of fibrous tissue encases the hilar area, possibly even distorting and fixing the pelvis. The UPJ may be distorted as well. The upper ureter initially courses laterally, and it, too, may be encased in this fibrous matting. The pelvis is elongated and narrow, and calyces, especially the superior calyx, may be stretched. The blood supply may vary widely, depending on the direction and degree of rotation. The vasculature may consist of a single vessel with or without multiple additional branches entering the parenchyma along the course of the renal artery. There also may be a polar vessel in conjunction with the main renal artery. The vascular orientation around the kidney provides the only clue to the type and extent of renal rotation.

Symptoms. Rotation anomalies, per se, do not produce specific symptoms. The excessive amount of fibrous tissue encasing the pelvis, UPJ, and upper ureter, however, may lead to varying degrees of hydronephrosis. Vascular compression from an accessory or main renal artery or distortion of the upper ureter or UPJ may contribute to intermittent obstruction.

Diagnosis. The diagnosis should be considered when a renal calculus is detected in an abnormal location, but confirmation should be obtained from a renal sonogram, CT, MRU, or retrograde pyelogram. These studies show the abnormal orientation of the renal pelvis and calyces, a flattened and elongated pelvis, a stretched superior calyx with blunting of the remaining calyces, and a laterally

displaced upper third of the ureter. Bilateral malrotation is not uncommon and may suggest the diagnosis of a horseshoe kidney. However, careful inspection for an isthmus and observation of the lower pole renal outline should distinguish the two entities.

Prognosis. Malrotation does not impair renal function. Hydronephrosis resulting from impaired urinary drainage may lead to infection and calculus formation.

ANOMALIES OF RENAL VASCULATURE

Aberrant, Accessory, or Multiple Vessels

The kidney is divided into various segments, each supplied by a single “end” arterial branch that usually courses from one main renal artery. The correct term to describe any kidney supplied by more than one vessel is *multiple renal arteries*. The terms *anomalous vessels* or *aberrant vessels* should be reserved for those arteries that originate from vessels other than the aorta or main renal artery. The term *accessory vessels* denotes two or more arterial branches supplying the same renal segment.

Incidence. Between 71% (Merklin and Michele, 1958) and 85% (Geyer and Poutasse, 1962) of kidneys have one artery that supplies the entire renal parenchyma. A slightly higher percentage of right-sided kidneys have a single renal artery compared with left-sided organs (Geyer and Poutasse, 1962). True aberrant vessels are rare, except in cases with renal ectopia, with or without fusion, and in individuals with a horseshoe kidney (Degani et al, 2010).

Embryology. The renal arterial tree is derived from three groups of primitive vasculature that coalesce to form the mature vascular pattern for all retroperitoneal structures. The cranial group consists of two pairs of arteries dorsal to the suprarenal gland that shift dorsally to form the phrenic artery. The middle group is made up of three pairs of vessels that pass through the suprarenal area and retain the same lateral position, becoming the adrenal artery. Finally, the caudal group of four paired arteries cross ventral to the suprarenal area and become the main renal artery. Sometimes the most inferior pair from the middle group joins them (Guggemos, 1962). It is believed that during renal migration this network of vessels selectively degenerates, and the remaining adjacent arteries assume a progressively more important function. By a process of elimination, one primitive renal arterial pair eventually becomes the dominant vessel, the completed process being dependent on the final position of the kidney (Graves, 1956). Polar arteries or multiple renal arteries to the normally positioned kidney represent a failure of complete degeneration of all primitive vascular channels. The multiple vessel pattern that has been described for renal

ectopia should be considered as an arrested embryonic state for that particular renal position (Gray and Skandalakis, 1972a).

Description. Based on vascular supply, the renal parenchyma is divided into five segments: apical, upper, middle, lower, and posterior. The main renal artery divides initially into an anterior and posterior branch. The anterior branch almost always supplies the upper, middle, and lower segments of the kidney. The posterior branch invariably supplies the posterior and lower segments (Sampaio and Aragao, 1990a). The vessel to the apical segment has the greatest variation in origin; it arises from (1) the anterior division (43%), (2) the junction of the anterior and posterior divisions (23%), (3) the mainstem renal artery or aorta (23%), or (4) the posterior division of the main renal artery (10%) (Graves, 1954). Rarely the upper segment is supplied from a branch totally separate from the main renal artery (Merklin and Michele, 1958). Sampaio and Aragao (1990a, 1990b) beautifully depicted in endocasts the arterial and venous tree of the kidney and its relationship to the collecting system. These investigations showed that the least likely areas to encounter vessels when entering the collecting system, either endourologically or with open surgery, are directly end-on through a fornix or inferiorly on the posterior aspect of the pelvis. Shoja and colleagues (2008) studied the perihilar (extraparenchymal) branching patterns and morphologies of the renal artery. A “fork” pattern with a common branching point (usually duplicated) was the most commonly observed extrarenal division and branching pattern of the main renal artery. They conclude that perihilar branching of the main renal artery was highly variable, with predictable patterns in the majority of kidneys. This information is useful for the transplant surgeon when interpreting radiodiagnostics of the renal hilum.

The lower renal segment, however, is often supplied by an accessory vessel (Fig. 130-20). This vessel is usually the most proximal branch when it arises from the main renal artery or its anterior division (Graves, 1954). However, it may originate directly from the aorta near the main renal artery, or it may be aberrant, arising from the gonadal vessel. Merklin and Michele (1958) performed an extensive study of the variant renal and suprarenal blood supply. Sampaio and Aragao (1990b) have studied the venous drainage of the kidney, and they noted a close association between the inferior branch to the main renal vein and the anterior inferior aspect of the renal pelvis in 40% of kidneys.

Symptoms. Symptoms attributable to renal vascular anomalies are those that might result from inadequate urinary drainage. Multiple,

aberrant, or accessory vessels may constrict an infundibulum, a major calyx, or the UPJ (Yen et al, 2004). Pain and hematuria secondary to hydronephrosis, UTI, or calculus may result.

Diagnosis. Precise anatomic resolution of vascular variants and associated disease states can be obtained using 3D power Doppler ultrasonography, CT, or MRI (Degani et al, 2010).

Prognosis. Hydronephrosis secondary to a vascular anomaly such as a lower pole crossing vessel is a very rare finding, especially when one considers the relative frequency of all renal vascular variations. Hypertension is no more frequent in patients with multiple renal arteries than in those with a single vessel (Geyer and Poutasse, 1962).

Renal Artery Aneurysm

Aneurysmal dilation was the first disease process of the renal artery to be recognized (Poutasse, 1957) and was considered a rare occurrence until selective renal angiography became widely available. Since then, the overall incidence has been calculated as between 0.1% and 0.3%. Abeshouse (1951) classified renal artery aneurysms (RAAs) as follows: saccular, fusiform, dissecting, and arteriovenous. The saccular aneurysm, a localized outpouching that communicates with the arterial lumen by a narrow or wide opening, is the most common type, accounting for 93% of all aneurysms (Zinman and Libertino, 1982). When the aneurysm is located at the bifurcation of the main renal artery and its anterior and posterior divisions, or at one of the more distal branchings, it is considered to be congenital in origin and is called the fusiform type (Poutasse, 1957). The presence of similar aneurysms at branching points in the vasculature of other organ systems attests to this possible origin (Lorentz et al, 1984). Acquired aneurysms may be located anywhere and may result from inflammatory, traumatic, or degenerative factors. A localized defect in the internal elastic tissue and the media allows the vessel to dilate at that point. It is a true aneurysm, because its walls are composed of most of the layers that make up the normal artery (Poutasse, 1957). The outpouchings may vary in size from 1 to 2 cm up to 10 cm (Garritano, 1957), but 90% are smaller than 2 cm. There is no absolute predilection for side, but the right appears to be favored, and bilateral aneurysms are seen in 15% (Pfeiffer et al, 2003).

Almost half of RAAs are silent, especially in children (Sarker et al, 1991). Some produce symptoms at a later age, because the size of the aneurysm increases with time. Pain (15%), hematuria

Figure 130-20. Nine-year-old girl with intermittent left flank pain, nausea, and vomiting. A, Color Doppler ultrasound study shows normal left renal artery and lower pole accessory vessel (arrow). B, Oblique sagittal view shows left lower pole accessory vessel (arrow) supplying the lower pole of the kidney, causing intermittent left ureteropelvic junction obstruction.

(microscopic and macroscopic) (30%), and hypertension (55%) secondary to compression of adjacent parenchyma or to altered blood flow within the vascular tree can occur (Bulbul and Farrow, 1992). The hypertension is renin-mediated and secondary to relative parenchymal ischemia (Lorentz et al, 1984). Thirteen cases of hydronephrosis secondary to an adjacent renal vessel aneurysm were noted (Miyagawa et al, 2001).

The diagnosis is suspected when a pulsatile mass is palpated in the region of the renal hilum or when a bruit is heard on abdominal auscultation. A wreathlike calcification in the area of the renal artery or its branches (30%) is highly suggestive (Silvis et al, 1956). RAAs can be evaluated with color Doppler sonography (Bunchman et al, 1991), spiral CT, 3D MRA, or digital subtraction arteriography (González et al, 2014).

Many asymptomatic RAAs come to light during a workup of uncontrolled hypertension (35%), whereas 26% are diagnosed when angiography is performed for other reasons (Hupp et al, 1992). The indications for treatment of RAAs remain controversial (González et al, 2014). It is generally agreed that treatment is indicated for those presenting with rupture or are at a high risk for rupture. High risk for rupture is associated with rapidly expanding RAAs and pregnant females or those who are considering pregnancy. More than 30 cases of a ruptured aneurysm during pregnancy have been reported (Lacroix et al, 2001). In addition, intervention is indicated for RAAs larger than 2.0 cm or for individuals with symptoms including uncontrolled hypertension from renal artery stenosis, flank pain, hematuria, or renal ischemia/infarction resulting from embolization from the aneurysm. Caution is advised because flank pain and hematuria may have alternative etiologies (González et al, 2014). The likelihood of spontaneous rupture (about 10%), with its dire consequences, dictates emergency treatment. Open surgical or endovascular techniques should be performed electively for those at high risk for rupture (González et al, 2014).

KEY POINTS: RENAL ARTERY ANEURYSM

- The overall incidence of RAA has been calculated to be between 0.1% and 0.3%.
- Most RAAs are silent, especially in children. Many asymptomatic RAAs are diagnosed during an evaluation of hypertension.
- The diagnosis may be suspected with a pulsatile mass in the region of the renal hilum or when an abdominal bruit is heard. A wreathlike calcification in the area of the renal artery or its branches (30%) is highly suggestive.

Renal Arteriovenous Fistula

Although rare, renal arteriovenous fistulas (AVFs) have been diagnosed with increasing frequency. Two types exist, congenital and acquired (Maldonado et al, 1964), with the latter (secondary to trauma, inflammation, renal surgery, or percutaneous needle biopsy) accounting for the increase in incidence. Only the congenital variant is discussed here.

Fewer than 25% of all AVFs are congenital, with only 91 reported cases (Takaha et al, 1980). They are identifiable by their cirroid configuration and multiple communications between the main or segmental renal arteries and the venous channels (Crummey et al, 1965; Cho and Stanley, 1978). Although congenital, they rarely present clinically before the third or fourth decade. Women are affected three times as often as men, and the right kidney is involved slightly more often than the left (Ishikawa et al, 2004). The lesion is usually located in the upper pole (45% of cases), but not infrequently it may be found in the midportion (30%) or in the lower pole (25%) of the kidney (Yazaki et al, 1976).

The condition is thought either to be present at birth or to result from a congenital aneurysm eroding into an adjacent vein (Thomason et al, 1972). The pathophysiology involved in the

shunting of blood, which bypasses the renal parenchyma and rapidly joins the venous circulation and returns to the heart, results in a varied clinical picture. The symptoms are based on the age and size of the AVF (Messing et al, 1976).

The hemodynamic derangement often produces a loud bruit in 75% of cases. Diminished perfusion of renal parenchyma distal to the fistulous site leads to relative ischemia and renin-mediated hypertension in approximately 50% (McAlhany et al, 1971). The increased venous return and high cardiac output with concomitant diminution in peripheral resistance may result in left ventricular hypertrophy and subsequent high-output cardiac failure in 50% of cases (Maldonado et al, 1964). Macroscopic and microscopic hematuria occurs in more than 75% of affected individuals because of the proximity of the collecting system (Montoya et al, 2004). Although flank or abdominal pain may be present, a mass is rarely palpable (10%).

Three-dimensional Doppler sonography and MRA are accurate and noninvasive tests (Mohaupt et al, 1999; Ishikawa et al, 2004), but selective renal arteriography or digital subtraction angiography is the most definitive method for diagnosing the lesion. A cirroid appearance with multiple small, tortuous channels; prompt venous filling; and an enlarged renal, and possibly gonadal, vein are pathognomonic for arteriovenous malformation (AVM) (DeSai and DeSautels, 1973).

The symptomatic nature of this lesion, which causes progressive alterations in the cardiovascular system, often dictates surgical intervention. The congenital variant rarely behaves like its acquired counterpart, which may disappear spontaneously after several months. Nephrectomy, partial nephrectomy, vascular ligation (Boijssen and Kohler, 1962), selective embolization (Bookstein and Goldstein, 1973), and balloon catheter occlusion (Bentson and Crandalls, 1972) have been used to obliterate the fistula.

ANOMALIES OF THE COLLECTING SYSTEM

Calyceal Diverticulum

A calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or less commonly with the renal pelvis through a narrow isthmus (Estrada et al, 2009). This abnormality, first described by Rayer in 1841, may be multiple, with the upper calyx most frequently affected.

In the past, an incidence of 4.5 per 1000 had been reported (Timmons et al, 1975). A similar incidence was noted both in children and in adults, with no predilection for either side or gender. Most diverticula, labeled type I, occur adjacent to an upper or, occasionally, a lower pole calyx. Type II diverticula are larger, communicate with the renal pelvis, and tend to be symptomatic (Wulfsohn, 1980).

Congenital and acquired factors have been suggested to explain the formation of calyceal diverticula. The similar incidence in children and adults is consistent with an embryologic etiology (Middleton and Pfister, 1974). At the 5-mm stage of the embryo, ureteral branches of the third and fourth generation, which ordinarily degenerate, may persist as isolated branches, resulting in the formation of a calyceal diverticulum (Lister and Singh, 1973).

A localized cortical abscess draining into a calyx has also been postulated as an etiologic factor. Other proposed causes include obstruction from stones or infection within a calyx, progressive fibrosis of an infundibular stenosis, renal injury, achalasia, and spasm or dysfunction of one of the supposed sphincters surrounding a minor calyx (Siegel and McAlister, 1979; Patriquin et al, 1985). Vesicoureteral reflux has also been considered an etiologic factor. Amar (1975) postulated that calyceal tubular backflow of infected urine could result in abscess formation and parenchymal injury leading to diverticular formation. Small diverticula are usually asymptomatic and are found incidentally by ultrasonography, CT, or MRI. These diverticula tend to distend progressively with trapped urine (Amar, 1975; Siegel and McAlister, 1979; Patriquin et al, 1985). Infection, milk of calcium (Patriquin et al, 1985),

Figure 130-21. Lower pole calyceal diverticulum. A, Sagittal sonogram. B, Sequence of coronal T2 images. C, Sagittal sonogram shows small stone within a diverticulum. D, Color Doppler sonogram demonstrates absence of flow. (B, Courtesy Dr. Sara Milla.)

or true stone formation are complications of stasis or obstruction that can produce symptoms ([Lister and Singh, 1973](#); [Siegel and McAlister, 1979](#)) ([Fig. 130-21](#)). Hematuria, pain, and UTI may be seen in the presence of stones, which may be present in almost 40% of patients.

KEY POINTS: CALYCEAL DIVERTICULUM

- A calyceal diverticulum is a cystic cavity within the kidney that is lined by transitional epithelium and communicates with a calyx or, less commonly, with the renal pelvis through a narrow isthmus.
- The incidence based on excretory urography is about 4.5 per 1000.
- The diagnosis is best made by CT or MRU.
- Laparoscopy by a retroperitoneal approach for marsupialization of the diverticulum, fulguration of the epithelial lining, and percutaneous marsupialization/ablation are treatment options.

The diagnosis is suggested on ultrasonography but is confirmed on CT scan or MRU ([Estrada et al, 2009](#)) (see [Fig. 130-21](#)). Delayed films demonstrate pooling of contrast material in the diverticulum. Ultrasonography delineates a fluid-filled area more centrally located near the collecting system than a simple renal cyst (see [Fig. 130-21](#)). When it is filled with microcalculi, ultrasonography characteristically demonstrates a layering effect, within the diverticulum, between clear fluid above and echo-dense debris without shadowing below ([Patriquin et al, 1985](#)). Ultrasonography will image the milk of calcium within the diverticulum as the patient changes position.

Patients who are asymptomatic do not require treatment but should be followed periodically with ultrasonography. [Estrada and colleagues \(2009\)](#) reported 10 of 23 calyceal diverticula (43%) that required treatment at a mean of 27 ± 25 months after initial diagnosis. Most commonly, these children presented with febrile UTI. The indications for surgery included enlargement of the diverticulum associated with pain or infection, abscess formation, urosepsis, and symptomatic calculus formation. Percutaneous ablation of the communication and fulguration of the diverticular lining was used until 1995. Although percutaneous ablation remains a viable

treatment alternative, the availability of pediatric laparoscopic equipment has led to the retroperitoneal laparoscopic approach for marsupialization of the diverticulum and fulguration of the epithelial lining (Estrada et al, 2009). Ureteroscopy with enlargement of the diverticular communication and removal of the stones has also been reported (Baldwin et al, 1998).

Hydrocalycosis

Hydrocalycosis is a rare cystic dilation of a major calyx with a demonstrable connection to the renal pelvis (Fig. 130-22).

Dilation of the upper calyx resulting from obstruction of the upper infundibulum by vessels or stenosis has been described (Johnston and Sandomirsky, 1972). Cicatrization of an infundibulum may result from infection or trauma or without an obvious etiology (Williams and Mininberg, 1968). It has been postulated that achalasia of a ring of muscle at the entrance of the infundibulum into the renal pelvis causes a functional obstruction (Williams and Mininberg, 1968).

Mild upper calyceal dilation caused by partial infundibular obstruction is relatively common but usually asymptomatic. Although the most frequent presenting symptom is upper

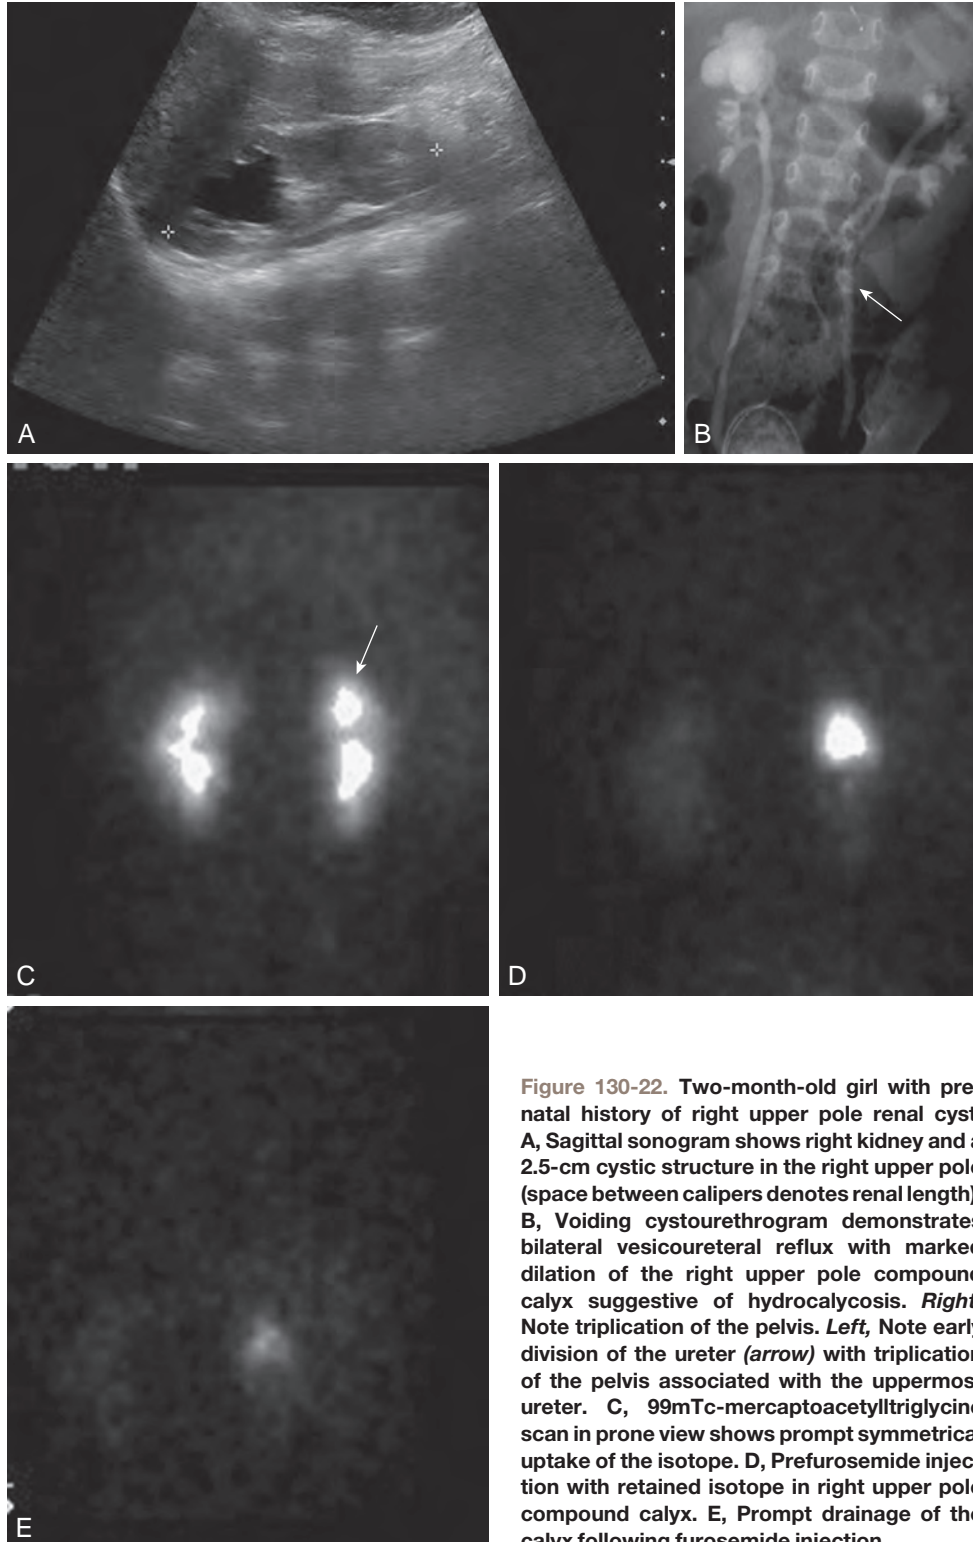

Figure 130-22. Two-month-old girl with pre-natal history of right upper pole renal cyst. **A**, Sagittal sonogram shows right kidney and a 2.5-cm cystic structure in the right upper pole (space between calipers denotes renal length). **B**, Voiding cystourethrogram demonstrates bilateral vesicoureteral reflux with marked dilation of the right upper pole compound calyx suggestive of hydrocalycosis. **Right**, Note triplication of the pelvis. **Left**, Note early division of the ureter (arrow) with triplication of the pelvis associated with the uppermost ureter. **C**, ^{99m}Tc -mercaptoacetyltriglycine scan in prone view shows prompt symmetrical uptake of the isotope. **D**, Prefurosemide injection with retained isotope in right upper pole compound calyx. **E**, Prompt drainage of the calyx following furosemide injection.

abdominal or flank pain, hydrocalycosis may be detected on prenatal ultrasonography (see Fig. 130-22). On occasion, a mass may be palpated. Stasis can lead to hematuria, urinary infection, or both.

Hydrocalycosis must be differentiated from multiple dilated calyces secondary to ureteral obstruction, calyceal clubbing as a result of recurrent pyelonephritis or medullary necrosis, renal tuberculosis, a large calyceal diverticulum, and megacalycosis.

Megacalycosis

Megacalycosis is defined as nonobstructive enlargement of calyces resulting from malformation of the renal papillae (Fig. 130-23). The calyces are generally dilated and malformed and may be increased in number (12 to 20) (Pieretti-Vanmarcke et al, 2009). The renal pelvis is not dilated, nor is its wall thickened, and the UPJ is normally funneled without evidence of obstruction. The cortical tissue around the abnormal calyx is normal in thickness. The medulla, however, is underdeveloped and assumes a falciform (crescent) or semilunar appearance instead of its normal pyramidal

shape. The collecting tubules are not dilated but are definitely shorter than normal, and they are oriented transversely rather than vertically from the corticomedullary junction (Puigvert, 1963). A mild disorder of maximal concentrating ability has been reported (Gittes and Talner, 1972), but acid excretion is normal after an acid load (Vela-Navarrete and Garcia Robledo, 1983). Other functions of the kidney such as glomerular filtration, renal plasma flow, and isotope uptake also are not altered (Gittes, 1984).

Megacalycosis is congenital and has been diagnosed prenatally (Vidal Company et al, 2001). It occurs predominantly in males with a ratio of 6:1 and has been found only in Caucasians. Bilateral disease has been seen almost exclusively in males, whereas segmental unilateral involvement occurs only in females (Cacciaguerra et al, 1996).

It was theorized by Puigvert (1964) and endorsed by Johnston and Sandomirsky (1972) that there is transient delay in the recanalization of the upper ureter after the branches of the UB hook up with the metanephric blastema. This produces transient obstruction when the glomeruli start producing urine. The fetal calyces may

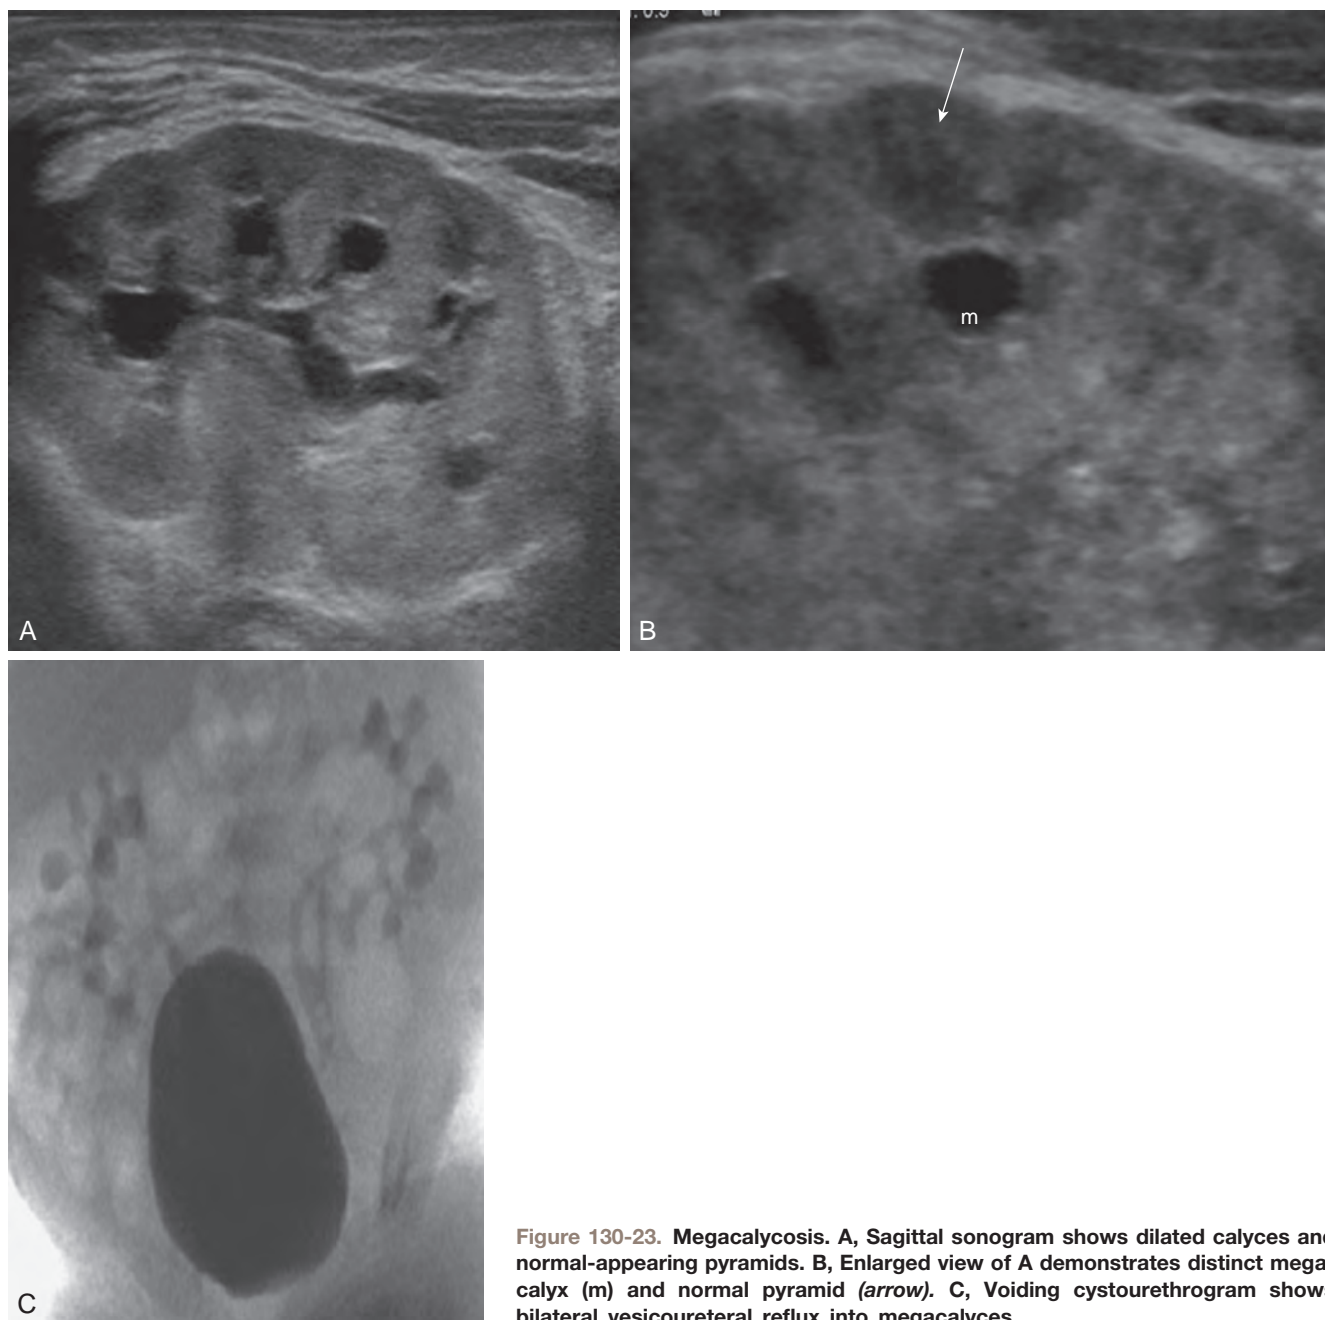

Figure 130-23. Megacalycosis. A, Sagittal sonogram shows dilated calyces and normal-appearing pyramids. B, Enlarged view of A demonstrates distinct megacalyx (m) and normal pyramid (arrow). C, Voiding cystourethrogram shows bilateral vesicoureteral reflux into megacalyces.

dilate and retain their obstructed appearance, despite the lack of evidence of obstruction in postnatal life (Gittes and Talner, 1972). The increased number of calyces may be an aborted response by the branching UB to the obstruction.

The abnormality is usually diagnosed during radiographic evaluation of a UTI or of other congenital anomalies (Arambasic et al, 2003). Adults frequently present with hematuria secondary to renal calculi.

The calyces are dilated and are usually increased in number, but the infundibuli and pelvis may not be enlarged. Although the UPJ does not appear obstructed, there may be segmental dilation of the distal third of the ureter (Kozakewich and Lebowitz, 1974). A normal-caliber ureter was interposed between the two entities. This anatomic picture may be mistaken for congenital ureteropelvic, ureterovesical junction obstruction, or infundibular stenosis (Pieretti-Vanmarcke et al, 2009). Diuretic renography shows a normal pattern for uptake and washout of the isotope (Gomez Tellado et al, 1997). Long-term follow-up of these patients does not show progression of the anatomic derangement or functional impairment of the kidney (Gittes, 1984).

KEY POINTS: MEGACALYCOSIS

- Megacalycosis is a nonobstructive enlargement of calyces resulting from malformation of the renal papillae.
- Megacalycosis occurs predominantly in males with a ratio of 6:1. Bilateral disease has been seen almost exclusively in males, whereas segmental unilateral involvement occurs only in females.
- Long-term follow-up of patients with this anomaly does not usually show progression of the anatomic or functional status of the kidney.

Pseudotumors of the Kidney

A renal pseudotumor is a prominence of normal renal parenchyma simulating a mass on radiographic studies. One such entity consists of cortical tissue situated between the infundibula of the upper and middle calyces, which splays or distorts the renal sinus and is called a hypertrophied column of Bertin (Fig. 130-24). These columns of Bertin have a similar echotexture to the surrounding parenchyma (Zwirewich and Rowley, 1997; Bhatt et al, 2007).

Another renal pseudotumor is termed *lobar dysmorphism*. This refers to a complete renal lobe that is seated deeply in the kidney and contains not only the renal cortex but a centrally located, well-formed calyx. Contrast studies show early opacification of the ectopic cortex, with sequential visualization of the medulla followed by the calyx. The sonographic finding of the posterior calyx and the echolucent pyramid is diagnostic for lobar dysmorphism (Zwirewich and Rowley, 1997).

Infundibulopelvic Stenosis

Infundibulopelvic stenosis most likely forms a link between cystic dysplasia of the kidney and the grossly hydronephrotic organ (Uhlenhuth et al, 1990). This condition includes a variety of radiographically dysmorphic kidneys with varying degrees of infundibular or infundibulopelvic stenosis that may be associated with renal dysplasia (Fig. 130-25). It is believed that this was the result of extensive dysgenesis of the pyelocalyceal system but with preservation of renal function.

Infundibulopelvic stenosis is usually bilateral and is commonly associated with vesicoureteral reflux, suggesting an abnormality of the entire UB (Kelalis and Malek, 1981). Patients usually present with urinary infection, hypertension, or flank pain. Sometimes, an asymptomatic child with multiple anomalies is found to have this condition. Despite extensively dysmorphic kidney features, the function is either normal or only slightly affected (Kelalis and Malek, 1981). In Husmann's study of 21 patients with the longest follow-up to date (median of 11 years), 90% had bilateral renal disease (Husmann et al, 1994). Ten patients had bilateral infundibulopelvic stenosis, six had a contralateral dysplastic renal unit, and three had contralateral URA. Renal insufficiency or end-stage renal disease (ESRD) developed in eight patients (37%), all of whom had bilateral kidney anomalies. Renal biopsies in those with ESRD demonstrated renal dysplasia proximal to the stenotic infundibuli and varying degrees of glomerulosclerosis of the glomeruli that were not involved in the regions with dysplasia. They proposed that the decreased total functional renal tissue leads to hyperfiltration injury. They suggested that endoscopic or percutaneous surgery should be considered for increasing hydronephrosis (see Fig. 130-25). More recently, Nurzia and colleagues (2002) recommend monitoring of renal function to include a baseline and yearly serum creatinine level, estimation of glomerular filtration rate, and urinalysis. Prevention of hyperfiltration injury with calcium channel blocking agents, ACE inhibitors, and dietary restriction of protein should be considered when a decline in renal function occurs (Puddu et al, 2009).

Figure 130-24. Sonogram of (A) sagittal view of right kidney with hypertrophied column of Bertin (arrow). B, Sagittal view of right kidney showing lobar dysmorphism resulting from malrotation of the renal lobe. The findings of a central echolucent pyramid and a posterior calyx (arrow) are diagnostic.

(Courtesy Dr. Pasquale Casale.)

KEY POINTS: INFUNDIBULOPELVIC STENOSIS

- Infundibulopelvic stenosis most likely forms a link between cystic dysplasia of the kidney and the grossly hydronephrotic kidney.
- Infundibulopelvic stenosis is usually bilateral and is commonly associated with vesicoureteral reflux, suggesting an abnormality of the entire UB.

Bifid Pelvis

Approximately 10% of normal renal pelves are bifid, the pelvis dividing to form two major calyces first at, or just within, its entrance to the kidney. A bifid pelvis should be considered a normal variant.

If further division of the renal pelvis occurs, triplication of the pelvis may result, but this is extremely rare (see Fig. 130-22).

Sporadic Glomerulocystic Kidney Disease

Acquired Renal Cystic Disease

Calyceal Diverticulum (Pyelogenic Cyst)

Parapelvic and Renal Sinus Cysts

Congenital and acquired renal malformations constitute a wide spectrum of clinical entities. Ectopia and fusion anomalies are covered in another chapter. This chapter is devoted to those disorders that lead to dysgenesis of the kidney, cystic lesions of the kidney, or both.

Many of these conditions are related to maldevelopment of the kidney and urinary tract and are thus the result of anomalous genetic mechanisms, some of which are understood and others of which are not. A basic knowledge of molecular genetics is required to better understand normal renal development, absence of renal development, and the effects of genetic mutations and abnormal signaling proteins on renal maldevelopment and cystic diseases. Within this chapter, the relevant genetic processes are discussed as they relate to specific disease processes. Further discussion on the specific genes involved with renal development appears in Chapter 122 and in an article by [Glassberg in 2002](#).

OVERVIEW OF GENETICS

Genetic direction of kidney and urinary tract development results when a gene from a specific chromosomal area produces a protein product that then signals certain actions to occur within an individual cell or group of cells. This cellular differentiation is then responsible for the particular action of those cells. In general, when a gene is normal, its protein product is normal as well. When a gene is abnormal, it produces an abnormal protein that can lead to maldevelopment or disease. Obviously, with complex organogenesis, the process is not always this simple. Often, more than one gene can be responsible for a specific disease. For example, an abnormality of one of two genes is responsible for the entity tuberous sclerosis. One tuberous sclerosis gene, *TSC1*, is located on chromosome 9 and the second, *TSC2*, on chromosome 16.

Each gene within a cell is one of a set of two; each is called an *allele*. One defective allele may be the carrier for the defect. In [Knudson's \(1971\) two-hit theory](#), the first hit is an inherited mutation that is found in all cells of an individual (i.e., a

germline mutation). The second hit occurs when the wild-type, normal allele spontaneously mutates within a specific organ, although it may be a different mutation than in the primarily affected allele ([Knudson, 1971](#)). For example, the typical somatic cells in the kidney and all other cells of a patient with von Hippel-Lindau (VHL) disease typically are heterozygous for the *VHL* gene located on chromosome 3; that is, the mutant *VHL* allele is inherited and its mate is the normal wild-type allele. However, the configuration of wild-type *VHL* makes it prone to spontaneous mutation. If the wild-type allele develops a defect within the cells of a specific organ, those cells no longer are able to produce normal pVHL (VHL protein) with its suppressor properties. That organ then has the propensity to develop a tumor. The variability in manifestations of autosomal dominant polycystic kidney disease (ADPKD) may be related to a two-hit phenomenon as well. For example, ADPKD is a heterozygous condition in which one allele of the *PKD1* or *PKD2* set is responsible for the genetic transmission of the disease but may not be enough for cystogenesis. A spontaneous mutation of the wild-type allele may be responsible for cystogenesis or for other manifestations of the disease. [Qian and colleagues \(1996\)](#) suggested that the *PKD1* gene has an unusual genomic structure that makes it readily mutable for a second hit, and the timing of this second hit may account for the phenotypic variability within one family. The second hit itself may occur only in a few cells, possibly accounting for the fact that less than 1% of nephrons in ADPKD eventually develop cysts ([Qian et al, 1996](#)). Within a cyst, many but not all of the lining cells have lost their heterozygosity ([Brazier and Henske, 1997](#); [Qian et al, 1999](#)).

RENAL AGENESIS AND DYSPLASIA

There are many terms that can be used to describe anomalous development of the kidney. These terms are often used interchangeably and can result in great confusion. The definitions as adopted in 1987 by the American Academy of Pediatrics (AAP) Section on Urology ([Glassberg et al, 1987](#)) are used in this chapter.

Renal Agenesis

Renal agenesis, or absent kidney development, can result from anomalous development of the wolffian duct, ureteric bud, and/or metanephric blastema. Bilateral agenesis occurs in 1 of every 4000 births and has a male predominance (Potter, 1965). Fetal demise occurs secondary to the lack of fetal urine production and subsequent oligohydramnios. Affected infants are born with immature lungs and pneumothorax, Potter facies (hypertelorism, prominent inner canthal folds, and recessive chin), and orthopedic defects secondary to intrauterine compression. Most cases of bilateral agenesis are sporadic, and many are associated with other congenital anomalies, including urogenital sinus defects.

Unilateral agenesis is more common, with an incidence of 1 in 450 to 1000 births (Kass and Bloom, 1992). Again, a wolffian duct abnormality is often the cause, and associated other wolffian and müllerian abnormalities may also be present, such as malformation of the ipsilateral uterine horn, fallopian tube, or ovary in the female or absence of the ipsilateral testis, vas deferens, or seminiferous tubules in the male. Mayer-Rokitansky-Küster-Hauser syndrome refers to a group of associated findings that include unilateral renal agenesis or renal ectopia, ipsilateral müllerian defects, and vaginal agenesis. Of men with unilateral or bilateral congenital absence of the vas deferens, 26% or 11%, respectively, had renal agenesis. Congenital bilateral agenesis of the vas deferens is also an expected finding in male patients with cystic fibrosis. Cystic fibrosis transmembrane conductance regulator (*CFTR*) gene mutations frequently contribute to maldevelopment of the vas deferens, but vasal agenesis can occur without any evidence of *CFTR* defects. *CFTR* abnormalities are rarely detected in men with congenital absence of the vas deferens and renal anomalies (Schlegel et al, 1996).

Unilateral renal agenesis can also be associated with other urologic abnormalities in 48% of patients, including primary vesicoureteral reflux (28%), obstructive megaureter (11%), and ureteropelvic junction obstruction (UPJO) (3%) (Cascio et al, 1999). These findings are similar to those associated with unilateral multicystic kidney disease, suggesting the possibility that some absent kidneys represent involuted multicystic dysplastic kidneys (MCDKs).

Additional reading on renal agenesis may be found in Chapter 130.

KEY POINTS: RENAL AGENESIS

- Bilateral renal agenesis is associated with oligohydramnios and Potter facies (hypertelorism, prominent inner canthal folds, and recessive chin).
- Unilateral agenesis is often associated with other genitourinary anomalies, and these patients should be appropriately screened.

Dysplasia

Definition

Renal dysgenesis is defined as maldevelopment of the kidney that affects its size, shape, or structure. It is composed of two primary subtypes, the first of which is dysplasia. The term *dysplasia*, while literally and most simply is defined as “abnormal tissue,” specifically, as it relates to the kidney, can only truly be defined on the basis of histopathology. **Dysplasia is a histologic diagnosis made by the presence of embryonic, immature mesenchyme, and primitive renal components.** The differentiation of the metanephros into mature renal components halts at some point along the developmental pathway, often because of an error in the wolffian duct–ureteric bud–metanephric blastema interaction. Common histologic features include distortion of renal architecture, immature or primitive glomeruli, nephron precursors such as comma- and S-shaped bodies, and cartilage and tubules encircled by collars

Figure 131-1. Primitive duct lined with columnar epithelial cells. Note concentric arrangement of spindle mesenchymal cells around the duct. Special staining is required to demonstrate smooth muscle cells.

of fibromuscular cells (referred to as *primitive ducts*) (Fig. 131-1). Ericsson and Ivemark (1958) considered these primitive ducts to be the sine qua non finding of all dysplasia. Cysts may or may not be present. The cause of the development of dysplasia appears to be twofold: (1) a primary, inherent abnormality in the differentiation of the nephron and collecting duct, often with an underlying genetic cause, and (2) a secondary cause resulting from congenital urinary tract obstruction.

KEY POINTS: DYSPLASIA

- The hallmark of dysplasia is the primitive duct, a duct encircled by a collar of fibromuscular cells.
- Dysplasia in its truest form is a histopathologic definition, not a clinical one.
- Dysplasia often is associated with ureteric bud anomalies and/or urinary tract obstruction.

Etiology

Renal dysplasia is the primary cause of childhood end-stage renal disease (ESRD), and two main theories have been considered in its pathogenesis: (1) a primary failure of ureteric bud activity and (2) a disruption in renal development produced by fetal urinary outflow impairment (obstruction). Mackie and Stephens (1975) described the ureteric bud theory, suggesting that ectopic (cephalad or caudal) ureteric bud formation leads to abnormal ureteric orifice location either laterally (often leading to vesicoureteral reflux) or distally (often leading to ureteral obstruction). Normal nephrogenesis is dependent on the ureteric bud meeting the center of the metanephric mesenchyme so that nephrogenesis is appropriately induced by the ureteric bud. However, an abnormally located ureteric bud would be expected to penetrate into a peripheral, degenerating area of the metanephric blastema. The result is a marginal (i.e., hypoplastic or dysplastic) kidney. In cases of dysplasia that are associated with an ectopic ureter, it is not clear if it is the obstruction, aberrant ureteric bud–metanephros interaction, or some other factor that leads to the dysplasia. Dysplasia associated with vesicoureteral reflux would also be included in this category.

Currently, there is no direct experimental evidence to prove that an abnormal ureteric bud site leads to ureteric bud penetration at a peripheral area of the blastema. However, there are substantial data to support the idea that defects in genetic and

apoptotic pathways can affect ureteric bud formation, branching morphogenesis within the metanephric blastema, and normal nephrogenesis (e.g., *RET*, *RAR*, *BMP4*, *SLIT2-ROBO2*, *COX-2*, *AT2*, *Fgfr2*) (Mendelsohn et al, 1994; Norwood et al, 2000; Pope et al, 2001; Grieshammer et al, 2004; Thomas et al, 2005; Bates, 2011). The genetic defect at each point may be the same, but the downstream pathway associated with the defect may vary for each process.

Animal studies of fetal urinary tract obstruction generate some but not all of the anatomic and histopathologic features of human renal dysplasia. Findings in these animal studies include dilation at various segments of the nephron and collecting duct, inhibition of nephron development in the nephrogenic zone, architectural disorganization, and the appearance of primitive glomeruli as well as S-shaped bodies and cysts. At times, obstruction in these animal models can even lead to de-differentiation of certain cells. An example is the conversion of renal epithelial cells back into mesenchymal cells and even of mesenchymal cells into myofibroblasts (Peters et al, 1992; Nguyen et al, 1999; Matsell and Tarantal, 2002). Dysplasia arising from obstruction typically appears at the periphery of the kidney, at the nephrogenic zone, and frequently with subcapsular cysts. This type usually develops later in gestation, as in the case of posterior urethral valves (PUVs) (Fig. 131-2).

Figure 131-2. Histologic specimen of a nonfunctioning reflux kidney in a patient with posterior urethral valves. Note presence of nests of cartilage (short arrows). Primitive ducts are scattered throughout the specimen (long arrow) (100×). The findings are compatible with dysplasia.

Dysplasia is associated with numerous genetic syndromes (Fraser syndrome; branchio-oto-renal [BOR] syndrome; renal-coloboma syndrome; Kallmann syndrome; Simpson-Golabi-Behmel syndrome; Smith-Lemli-Opitz syndrome; hypoparathyroidism, sensorineural deafness, and renal dysplasia [HDR] syndrome, and Townes-Brocks syndrome, to name a few). The kidney, in association with these conditions, may be composed mostly of normal functioning parenchyma with areas of dysplasia, or, alternatively, the entire kidney may be dysplastic or entirely absent.

On rare occasions, renal agenesis, renal dysplasia, multicystic dysplasia, and renal aplasia may appear in family members but heterogeneously. One family member may have renal agenesis while another has renal dysplasia and still another has a multicystic dysplastic or aplastic kidney. When all or part of this group of anomalies is seen in one family, an encompassing term for these four entities is used: *familial renal adysplasia*.

Ultrasonographically, dysplastic kidneys have a distinct appearance. The kidney is typically small and is hyperechogenic when compared with the liver. There is loss of the typical corticomedullary differentiation, and there is minimal distinction of the renal parenchyma and the perirenal fat (Fig. 131-3A). Cysts can be seen in conjunction with parenchymal dysplasia (Fig. 131-3B). These cysts can also develop from either abnormal development of the metanephric blastema or from distal obstruction. Again, the exact cause of the cyst formation can be unclear. The important point is that not all cysts are a result of dysplasia and not all dysplasia is associated with cysts.

HYPOPLASIA AND HYPODYSPLASIA

Renal Hypoplasia

Another form of renal dysgenesis is hypoplasia, which is defined as the underdevelopment of a tissue or organ and which is usually caused by a deficiency in the number of cells. Renal hypoplasia is a condition in which there is a reduction in the size of the functioning renal mass. Use of the term *hypoplasia* should be restricted to kidneys that have less than the normal number of calyces and nephrons but are not dysplastic or embryonic. These are kidneys that are morphologically normal but have either a reduced number of nephrons or smaller nephrons, although a hypoplastic kidney may have a normal nephron density despite its small size. Hypoplasia may be bilateral or unilateral. In unilateral cases, the other kidney usually shows greater compensatory growth than is characteristic in patients with renal atrophy caused by acquired disease. Many have used the term *hypoplasia* to describe small kidneys associated with vesicoureteral reflux. These kidneys often do not function and have dysplastic elements histologically. The term *hypoplasia* is

Figure 131-3. Ultrasonographic appearance of renal dysplasia. A, Classic dysplasia with hyperechogenic appearance of the kidney relative to the liver, a loss of normal corticomedullary differentiation, and dysmorphic calyces. B, Renal dysplasia accompanied by cysts. (Courtesy Marta Hernanz-Schulman, MD.)

thus technically incorrect, and a more appropriate term for these kidneys would be *congenital reflux nephropathy*. The terms *hypoplasia* and *congenital reflux nephropathy* should not, however, be used interchangeably. Small kidneys associated with reflux have been called *hypoplastic* in the past; however, now the term *reflux nephropathy* is used to describe the renal changes associated with reflux.

Hypodysplastic kidneys most often occur in conjunction with ectopic ureteric orifices, with the extent of dysplasia correlating with the degree of ectopia (Schwarz et al, 1981). However, hypodysplastic kidneys are seen in a few patients with normal ureteric orifices. In such patients, obstruction may or may not be present.

All forms of hypoplasia can be assessed by ultrasonography with measurement of the kidneys. The size will be reduced in all forms. Dilated calyces may also be seen. The collecting systems will be demonstrated by excretory urography if renal function is not sufficiently impaired to prevent this. Renal function is assessed biochemically and, if there is unilateral hypoplasia, by radionuclide studies.

Oligomeganephronia

First described in 1962 (Habib et al, 1962; Royer et al, 1962), oligomeganephronia is a type of renal hypoplasia that results from a quantitative defect of the renal parenchyma with a reduced number of nephrons and hypertrophy of each nephron. This condition differs histopathologically from simple hypoplasia in which the renal mass is reduced but the number of nephrons is normal. Oligomeganephronia may occur as a sporadic defect or in association with a number of syndromes. It is usually a bilateral condition, although a few instances of unilateral oligomeganephronia associated with contralateral renal agenesis have been reported (Griffel et al, 1972; Lam et al, 1982; Forster and Hawkins, 1994).

Etiology

Oligomeganephronia results from arrested development of the metanephric blastema at 14 to 20 weeks' gestation, with subsequent hypertrophy of glomeruli and tubules in the kidney. This hypertrophy and hyperfiltration results in further nephron injury and sclerosis. Eventually, this progressive loss of nephrons leads to ESRD. Although oligomeganephronia is associated with some genetic syndromes, most cases are sporadic. However, mutations in the paired-box transcription factor (*PAX2*) gene have been noted in persons with nonsyndromic oligomeganephronia (Salomon et al, 2001). Recently, mutations in the homeobox transcription factor (hepatocyte nuclear factor-1 β) have been described in association with oligomeganephronia (Bohn et al, 2003). It is interesting to note that the heterozygous mutation may be associated with development of the kidney lesion. Vascular abnormalities and accidents have been associated with this type of renal hypoplasia. The cause of most oligomeganephronia cases is unknown.

Clinical Features

Oligomeganephronia is a nonheritable congenital disorder, and boys appear to be affected more often than girls. It frequently is associated with low birth weight (2500 g). The condition is usually discovered within the first 2 years of life. In neonates, kidney disease is often suspected with spontaneous pneumothorax, feeding problems, or laboratory abnormalities. Oligomeganephronia typically manifests with anorexia, vomiting, dehydration, intense thirst, polyuria, and failure to thrive. It may also be incidentally diagnosed when renal anomalies are discovered in the evaluation of another illness. The creatinine clearance is abnormal (10 to 50 mL/min/1.73 m²), and the maximum specific gravity of the urine is 1.007 to 1.012. Moderate proteinuria may be present, but this is more likely to be a later finding. In neonates with oligomeganephronia, particular attention should be directed to diagnosis of associated syndromes, including BOR syndrome, acrorenal syndrome, and tapetoretinal dystrophy.

After the first year of life, individuals with oligomeganephronia most often have short stature, polyuria and polydipsia, or proteinuria. Renal function remains below normal (although stable) for many years. As the patient enters his or her teens, the creatinine clearance begins to drop rapidly. Marked proteinuria (2 g/24 hr) is common. Over a period of years, the kidney continues to atrophy with reduction in the number of tubules. Oligomeganephronia is a progressive disorder, and many patients go on to renal failure in the second decade.

Histopathology

Meticulous histologic examination of the kidney is the only way to establish an absolute diagnosis of oligomeganephronia. There is a reduced number of nephrons, which are all elongated (sometimes fourfold) and widened, particularly at the proximal end (Fig. 131-4). Immature glomeruli are often present. Existing glomeruli and tubules are enlarged. As the disease progresses, segmental sclerosis and hyalinosis of glomeruli are present. Tubular atrophy with interstitial fibrosis occurs. The renal artery is small.

Evaluation

Proteinuria is often the first laboratory manifestation of oligomeganephronia and precedes decline in renal function by several years. Other laboratory manifestations of renal failure are frequently present, including elevated blood urea nitrogen (BUN) and creatinine levels, hyponatremia, and metabolic acidosis. Advancing renal failure may result in secondary hyperparathyroidism and anemia as a result of erythropoietin deficiency. In terms of imaging studies, small kidney size depicted on renal ultrasonography (RUS) usually establishes the diagnosis of hypoplasia.

Treatment

In general, treatment is supportive and directed at maintaining normal biochemical balance, hemoglobin, and growth. High fluid intake and correction of salt loss and acidosis are the initial steps. Daily dietary protein should be limited to 1.5 g/kg during the stable phase (Royer et al, 1962). In addition, angiotensin-converting enzyme (ACE) inhibitors may be of benefit in slowing progression of renal failure, even if the patient has a normal blood pressure (BP). ESRD is managed by dialysis and transplantation. The allograft may come from a living related donor because the disease is not familial.

Ask-Upmark Kidney (Segmental Hypoplasia)

In 1929, Erik Ask-Upmark, a Swedish physician, described distinctive small kidneys in eight patients, seven of whom had malignant hypertension; six of these patients were adolescents. Subsequently, this problem was described histologically as focal renal hypoplasia resulting in a segmental renal scar. Segmental renal hypoplasia, or Ask-Upmark kidney, refers to situations of extreme acquired reflux nephropathy, and the patients (usually young women and girls) most frequently have hypertension. The lesions found in these kidneys are most likely acquired, possibly representing chronic atrophic pyelonephritis caused by vesicoureteral reflux, although some appear to be congenital. Segmental vascular (arterial) anomalies have also been cited as a possible cause for these lesions.

Clinical Features

Most patients are 10 years of age or older at diagnosis. The disease is associated with severe hypertension, sometimes with headaches, either alone or together with hypertensive encephalopathy (Rosenfeld et al, 1973) and with retinopathy in half of the patients (Royer et al, 1971).

Proteinuria and some degree of renal insufficiency may be present if the disease is bilateral. Approximately half of the patients

Figure 131-4. A, Mosaic photograph of two typical proximal tubules dissected from the kidney of a patient with oligomeganephronia. The silhouette in the top center is a diagrammatic representation to scale of an average proximal tubule from a kidney of an age-matched control. B, Enlargement of the inset in A showing the diverticula along the course of the nephron (arrows). (From Fetterman GH, Habib R. Congenital bilateral oligonephronic renal hypoplasia with hypertrophy of nephrons [oligomeganephronia]. *Am J Clin Pathol* 1969;52:199–207.)

in the series described by [Royer and colleagues \(1971\)](#) had these signs at diagnosis. The disorder is usually unilateral, producing a small kidney with deep, narrow, segmental scars (slit-scar) found in the midzone. These slit-scars are the classic radiographic finding. Although the scar can be detected with ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), the presence of a deep scar is often overlooked.

Histopathology

The Ask-Upmark kidney is smaller than normal—12 to 35 g ([Royer et al, 1971](#)). Its distinctive feature is one or more deep grooves on the lateral convexity, underneath which the parenchyma consists of tubules resembling those in the thyroid gland. Usually, the hypoplastic segments are easily distinguished from adjacent areas. The medulla consists of a thin band, and remnants of the corticomedullary junction and arcuate arteries are seen. Arteriosclerosis is common, and juxtaglomerular hyperplasia may be seen ([Bernstein, 1968](#); [Meares and Gross, 1972](#); [Kaufman and Fay, 1974](#); [Arant et al, 1979](#)) (Fig. 131-5).

Treatment

Abnormal renin secretion has been proposed as the cause of the hypertension; however, nephrectomy has been shown to normalize BP regardless of plasma renin activities ([Babin et al, 2005](#)). In

Figure 131-5. Typical microscopic pattern of segmental hypoplasia affecting the cortex with thyroid-like tubules, thick-walled arteries, and the absence of glomerulus. Note the sharp delineation from the surrounding normal kidney (bottom). Periodic acid-Schiff stain. (From Babin J, Sackett M, Delage C, et al. The Ask-Upmark kidney: a curable cause of hypertension in young patients. *J Hum Hypertens* 2005;19:315–6.)

patients with unilateral disease, partial or total nephrectomy may control the hypertension (Royer et al, 1971; Meares and Gross, 1972). Failure of this measure suggests an unrecognized scar or generalized arteriosclerosis in the remaining kidney (Arant et al, 1979). Bilateral disease with renal insufficiency usually is managed medically, although dialysis and transplantation may be needed. Correction of reflux may prevent further renal damage but probably will have no effect on the hypertension.

Renal Hypodysplasia

Hypodysplasia may be associated with a wide spectrum of urologic diseases, such as primary obstructive megaureter and UPJO, ureterocele, urethral obstruction, or prune-belly syndrome, to name a few. It has been previously mentioned that abnormal ureteric budding leads to abnormal renal development that often manifests as hypodysplasia. Lateral ureteral ectopia usually leads to vesicoureteral reflux and its associated forms of hypodysplasia—be it a developmental anomaly, the result of chronic pyelonephritis, or a combination of both. Medial ureteral ectopia, with or without the presence of a ureterocele, can often result in hypodysplasia as well. The renal cortex may be thin, secondary to hydronephrosis, or severely dysplastic, and perhaps with numerous small cysts.

According to Osathanondh and Potter (1964), PUVs may be associated with two types of renal hypodysplasia. In the less severe form, there are small, usually subcapsular cysts and nearly normal renal function. In the second form, the cysts are larger and more widely distributed, and numerous islands of cartilage are present. This form usually is associated with earlier onset and more severe obstruction and reflux (see Fig. 131-2).

The features of the prune-belly syndrome (absent abdominal musculature, triad syndrome) include grossly deformed kidneys, which may have various degrees of hypodysplasia. The ureters are wide and tortuous, often with large and laterally placed orifices. Urethral obstruction or atresia may be present in the most severe cases, but usually there is no lower urinary tract obstruction.

KEY POINTS: HYPOPLASIA AND HYPODYSPLASIA

- Hypoplasia and hypodysplasia often are associated with ectopic orifices and sometimes with obstruction.
- Oligomeganephronia is a condition with a reduced number of nephrons and hypertrophy of each nephron.
- Ask-Upmark kidneys have segmented dysplasia, are seen most frequently in association with reflux, and are often the cause of severe hypertension.

CYSTIC DISEASES OF THE KIDNEY

The kidney is one of the most common sites in the body for cyst formation. Renal cystic diseases encompass a broad spectrum of sporadic and genetically determined congenital or acquired conditions that have in common the presence of cysts in one or both kidneys. These diseases often require a multidisciplinary approach to evaluation and treatment.

Renal cysts are cavities derived primarily from tubules and are composed of a layer of partially de-differentiated epithelial cells enclosing a cavity filled with urine-like liquid or semisolid material. They may develop in any tubular segment between the Bowman capsule and the tip of the renal papilla, depending on the nature of the underlying disorder. Some cysts are saccular or fusiform structures that resemble diverticula. Other cysts may or may not communicate with a glomerulus, tubule, collecting duct, or calyx, or they may initially have communicated only to become isolated later. **Multicystic dysplasia is an exception in that it arises before formation of the nephron, from abnormal induction of metanephric development, from a primary abnormality**

of the nephrogenic blastema, or from obstruction occurring early in renal development. Another exception, benign multilocular cyst, represents a neoplastic growth.

The fundamental processes that are essential for the development and progressive enlargement of renal cysts include (1) proliferation of epithelial cells in segments of renal tubule, (2) accumulation of fluid within the expanding tubule segment, and (3) disturbed organization and metabolism of the extracellular matrix (Fig. 131-6).

An imbalance of the secretory and absorptive properties in proliferating epithelial cells leads to a net accumulation of fluid in otherwise normal renal tubules. Beyond the loop of Henle, tubule cells have the capacity to secrete solutes and fluid on stimulation with 3',5'-cyclic adenosine monophosphate (cAMP) (Wallace et al, 2001). This secretory flux operates in competition with the more powerful mechanism by which sodium (Na^+) is absorbed through apical epithelial Na^+ channels (ENaC). Under conditions in which Na^+ absorption is diminished, the net secretion of sodium chloride (NaCl) and fluid occurs.

Abnormalities of the extracellular matrix in and about renal cysts are seen in all cystic disorders. In the early stages of renal cyst development, changes in expression of collagen I and IV, metalloproteinase activators and inhibitors, integrins, and β -catenin may forecast a vital role for extracellular matrix remodeling in the pathogenesis of renal cysts. Recently, a hypomorphic mutation in the mouse laminin $\alpha 5$ gene was found to cause polycystic kidney disease (PKD) (Joly et al, 2006; Shannon et al, 2006).

Until recently, the mechanisms responsible for the abnormal differentiation and functional behavior of the epithelial cells that give rise to the cysts were largely unknown. Evidence now strongly suggests that a long-neglected structure, the primary cilium, is essential in maintaining epithelial cell differentiation. Structural and functional defects in the primary apical cilia of tubular epithelia may have a central role in determining cyst development and the abnormal differentiation and behavior of the cystic epithelium, and in various forms of human and rodent cystic diseases (Torres and Grantham, 2008). There have been several novel signaling pathways identified that are involved in the regulation of these epithelial cells and that are providing new opportunities for targeted therapies to slow and/or prevent cystogenesis (Blanco and Wallace, 2013; Choi et al, 2013; Mochizuki et al, 2013; Zhou et al, 2013).

Cystic kidneys of different causes may appear morphologically similar, whereas the same etiologic entity may cause a wide spectrum of renal abnormalities. For example, in ADPKD, tuberous sclerosis, VHL disease, and acquired renal cystic disease (ARCD), the cysts have a hyperplastic lining, sometimes with nodules of hyperplasia or polyps that project into the cyst lumen. However, these hyperplastic conditions are very different from one another. Another example of such similarities is the ectatic collecting ducts seen in two very different clinical entities, autosomal recessive polycystic kidney disease (ARPKD) and medullary sponge kidney.

Classification

In this chapter, the classification of renal cystic disease as outlined in 1987 by the Committee on Classification, Nomenclature, and Terminology of the AAP Section on Urology is used. **The primary distinction is between genetic (inheritable) and nongenetic (nonheritable) disease.** Box 131-1 gives an overview of characteristics associated with the various forms of cystic disease.

The terms multicystic and polycystic should not be confused, even though both terms literally mean “many cysts.” *Multicystic* typically refers to a dysplastic kidney resulting from aberrant renal development. *Polycystic* refers to renal units that developed in a normal fashion, all of which have no dysplasia and have nephrons throughout the kidney. The term *polycystic kidney disease* traditionally is used in reference to two conditions: ARPKD and ADPKD. Many of the PKD entities progress to renal failure as the nephrons become more diseased. In other conditions, such as tuberous sclerosis and VHL disease, there are hyperplastic cysts, and the

Figure 131-6. Evolution of cysts from renal tubules. Abnormal proliferation of tubule epithelium begins in a single cell after a “second-hit” process disables the function of the normal allele. Repeated cycles of cell proliferation lead to expansion of the tubule wall into a cyst. The cystic epithelium is associated with thickening of the adjacent tubule basement membrane and with an influx of inflammatory cells into the interstitium. The cystic segment eventually separates from the original tubule, and net epithelial fluid secretion contributes to the accumulation of liquid within the cyst cavity. (From Brenner BM, editor. *Brenner and Rector’s the kidney*. 8th ed. Philadelphia: Saunders; 2008. p. 1428.)

individual nephrons are normal. Only occasionally do the nephrons become compressed by the cysts or by associated tumors, and only in such situations does renal failure ensue.

Among the nonheritable cystic diseases, benign multilocular cysts, cystic renal cell carcinoma (RCC), and other variants are considered neoplasms. Medullary sponge kidney is a disease principally of dilated ectatic collecting ducts, with cysts playing a lesser role, although the size of the ducts by definition makes them cysts. The nephrons initially are normal.

Inheritable Cystic Disease

Genetic (inheritable) cystic diseases can be classified based on their mode of transmission: autosomal dominant, autosomal recessive, X-linked, and others. Some of these disorders are caused by a single gene defect, some by an X-linked gene defect, and others by chromosomal defects. The modes of inheritance of these diseases and the specific gene or gene locus, where identified, are summarized in Table 131-1.

AUTOSOMAL RECESSIVE (INFANTILE) POLYCYSTIC KIDNEY DISEASE

ARPKD is typified by relatively rapid, symmetrical, and bilateral enlargement of the kidneys in infants secondary to collecting duct cysts. It is invariably associated with some degree of congenital hepatic fibrosis (Zerres et al, 1988; Guay-Woodford and Desmond, 2003; MacRae Dell and Avner, 2003). ARPKD has been referred to as the “infantile” form in the past; however, the disease can occur in adolescents and young adults, although significantly less frequently. ARPKD has a spectrum of severity, with the most severe forms appearing earliest in life. If it is not apparent at birth, the disease will become apparent later in childhood (up to age 13 years or, rarely, up to age 20 years).

The reported incidence of ARPKD varies from 1 in 10,000 to 50,000 live births (Zerres et al, 1988; Kaplan et al, 1989a). However, as many as 50% of affected newborns die in the first few days of life, making for a significantly lower incidence among children who live for at least 1 year. Of those infants who survive the neonatal

BOX 131-1 Cystic Diseases of the Kidney**INHERITABLE**

Autosomal recessive (infantile) polycystic kidney disease
 Autosomal dominant (adult) polycystic kidney disease
 Juvenile nephronophthisis and medullary cystic disease complex
 Juvenile nephronophthisis (autosomal recessive)
 Medullary cystic disease (autosomal dominant)
 Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
 Familial hypoplastic glomerulocystic disease (autosomal dominant)
 Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel-Lindau disease)

NONHERITABLE

Multicystic kidney (multicystic dysplastic kidney)
 Benign multilocular cyst (cystic nephroma)
 Simple cysts
 Medullary sponge kidney
 Sporadic glomerulocystic kidney disease
 Acquired renal cystic disease
 Calyceal diverticulum (pyelogenic cyst)

period, approximately 50% are alive at 10 years of age (Kaplan et al, 1989a).

Genetics

Once the diagnosis of ARPKD is strongly suspected, referral for genetic evaluation and counseling is appropriate. A detailed history should be taken of at least three generations. **Because the disease is transmitted as an autosomal recessive trait, siblings of either sex have a 1 in 4 chance of being affected.**

Despite the clinical variability of ARPKD, it appears that only mutations of a single gene, named *PKHD1* and located on chromosome 6 (6p12), are responsible for the disease. The gene produces a protein called *fibrocystin* (also known as *polyductin*) (Onuchic et al, 2002; Ward et al, 2002). This protein is a member of a larger family of proteins involved in regulation of cell proliferation and of cellular adhesion and repulsion. More specifically, dysfunction of this protein mediates cystogenesis through dysfunction of the primary cilia of renal epithelial cell. It is highly expressed in the kidney, with levels also present in the liver and pancreas. It is localized to the branching ureteric bud, collecting ducts of the kidney, and biliary ducts, consistent with the phenotype seen in ARPKD, and it is often absent in the patients with ARPKD (Wilson, 2004; Al-Bhalal and Akhtar, 2008).

Clinical Features

Affected children typically have enlarged, echogenic kidneys in utero. Oligohydramnios is common because of the lack of normal urine production by the fetus. The infant often displays Potter facies and deformities of the limbs and may have respiratory distress as a consequence of pulmonary hypoplasia. The affected newborn usually has enormous, kidney-shaped, nonbosselated flank masses that are hard and do not transilluminate. In some cases, the kidneys are large enough to impede delivery. The infant's serum creatinine and BUN concentrations are those of the mother's at birth but soon begin to rise. Thirty percent to 50% of the affected individuals die shortly after birth as a result of uremia or respiratory failure (Kaplan et al, 1989b; Capisonda et al, 2003; Guay-Woodford, 2003). The earlier the age at which the disease is identified, the

more severe the disease. **No matter what the severity of the renal disease, all patients with ARPKD have liver involvement in the form of congenital hepatic fibrosis and vary in the degree of biliary ectasia and periportal fibrosis** (Habib and Bois, 1973; Kissane and Smith, 1975).

Patients who survive the neonatal period have a milder form of the disease and are likely to survive into adulthood. Some diagnosed as neonates can live beyond age 3 or 4 years before going into renal failure (Cole et al, 1987; Avni et al, 2002). **Hypertension and renal insufficiency are the major manifestations in surviving children, with liver disease becoming more prevalent in older patients.** The exact cause of hypertension remains unclear. Consequences of chronic renal insufficiency (e.g., growth failure, anemia, osteodystrophy) become more apparent as the children age. Renal calcifications occur commonly in patients with ARPKD.

Patients whose disease appears later in life develop renal failure and hypertension more slowly. In general, their clinical problems are the consequence of liver disease rather than the renal disease, with hepatic fibrosis leading to portal hypertension, esophageal varices, and hepatosplenomegaly. Hepatocellular function is rarely abnormal, with liver enzymes typically remaining normal. The kidneys in these patients are often normal in appearance.

No association of ARPKD with renal neoplasms has been reported to date.

Histopathology

The kidneys are symmetrically enlarged (up to 20 times their normal size) and retain a reniform configuration. The parenchyma exhibits small subcapsular cysts, representing generalized fusiform dilations of the collecting tubules radiating from the medulla to the cortex with their long axis perpendicular to the renal surface (Bisceglia et al, 2006). Almost 100% of collecting ducts are affected in the most severe cases. The cortex is crowded with minute cysts (Fig. 131-7A). The renal pedicle is normal, as are the renal pelvis and ureter.

ARPKD affects both the kidneys and the liver in approximately inverse proportions (Torres and Grantham, 2008). The disease may be viewed as a spectrum ranging from severe renal disease and mild liver changes at one extreme to mild renal damage and severe liver disease at the other. The form with severe renal disease is the most common and the one typically seen at or near the time of birth. The form with less severe renal disease and more significant liver damage is present in older children. **All children with ARPKD have lesions in the periportal areas of the liver** (Habib and Bois, 1973; Kissane and Smith, 1975) (Fig. 131-7B). Congenital hepatic fibrosis is characterized by enlarged and fibrotic portal areas with apparent proliferation of bile ducts, absence of central bile ducts, hypoplasia of the portal vein branches, and sometimes prominent fibrosis around the central veins. Bulbar protrusions from the walls of dilated ducts also occur, and bridges sometimes form. This malformation has been found to occur occasionally as an isolated event (Caroli disease), but most often it is associated with ARPKD (Torres and Grantham, 2008).

Evaluation

The diagnosis may be suspected from in utero ultrasound examination and may be associated with oligohydramnios, a finding secondary to low urinary output. **In both fetus and newborn, ultrasonography identifies bilateral, very enlarged, diffusely echogenic kidneys, especially when compared with the echogenicity of the liver** (Fig. 131-8A). The increased echogenicity is due to the presence of numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces. Compared with normal newborn kidneys, in ARPKD, the pyramids are hyperechogenic because they blend in with the rest of the kidney, and the kidneys typically have a homogeneous appearance (see Fig. 131-8A). In ADPKD, the cysts, if apparent in newborns, are usually diffuse and large (see Fig. 131-8B). Also included in the differential diagnosis is severe bilateral

TABLE 131-1 Characteristics of Major Inheritable and Nonheritable Cystic Kidney Diseases

DISEASE ENTITY	CHROMOSOMAL DEFECT	RENAL FINDINGS	EXTRARENAL MANIFESTATIONS
INHERITABLE			
Autosomal recessive polycystic kidney disease (ARPKD)	Chromosome 6	In newborn usually large, homogeneous, echogenic kidneys	Congenital hepatic fibrosis; biliary dysgenesis
Autosomal dominant polycystic kidney disease (ADPKD)	<i>PKD1</i> : chromosome 16 <i>PKD2</i> : chromosome 4 <i>PKD3</i> : not mapped	Renal cysts scattered throughout parenchyma; large kidneys	Diverticulitis; liver, spleen, pancreatic cysts; mitral valve prolapse; intracranial (berry) aneurysms
Juvenile nephronophthisis and medullary cystic disease complex Juvenile nephronophthisis (autosomal recessive) Medullary cystic disease (autosomal dominant)	Chromosome 2; not mapped	Cysts of corticomedullary junction; develop after onset of renal failure; always thickened tubular basement membrane	Retinitis pigmentosa (16%; also known as Senior-Loken syndrome); rarely skeletal abnormalities, hepatic fibrosis, Bardet-Biedl syndrome, ocular motor apraxia, and other neurologic defects
		Cysts of corticomedullary junction; develop before onset of renal failure; tubular basement membrane may not be thickened	None
Tuberous sclerosis (autosomal dominant)	<i>TSC1</i> : chromosome 9 <i>TSC2</i> : chromosome 16	Cysts and angiomyolipomas throughout kidney; cysts even present in utero; 3% incidence of RCC	Adenoma sebaceum; epilepsy; mental retardation; cranial tumors
von Hippel-Lindau disease (autosomal dominant)	Chromosome 3	Cysts, adenomas, and clear cell RCC (35%-38% of cases)	Cerebellar hemangioblastomas; retinal angiomas; pheochromocytomas; cysts of pancreas and epididymis
NONHERITABLE			
Multicystic dysplastic kidney	Renal maldevelopment with diffuse cysts and remnants of early metanephros; minimal, if any, nephron development; most frequent renal cystic disease in newborns		Unusual
Benign multilocular cyst	Benign cystic neoplasm of the kidney; remainder of kidney has normal nephrons that may be compromised by growing mass; present more often in males when younger than 4 yr and females when older than 30 yr		None
Simple cysts	Single or multiple cysts; normal nephrons throughout kidney; very common in normal kidneys with increasing age		None
Medullary sponge kidney	Ectatic collecting ducts; nephrons usually normal		None
Acquired renal cystic disease	Diffuse cysts; adenomas; occasionally RCC; increases with duration of ESRD		None

ESRD, end-stage renal disease; RCC, renal cell carcinoma.

Figure 131-7. Newborn with abdominal mass and pulmonary hypoplasia. Neither parent had a history of renal cysts. A, Renal histology demonstrates dilated ducts radiating out to the periphery of the kidney. B, On liver histology, ectatic biliary ducts are seen in the left half of the figure, and periportal fibrosis is seen at the upper edge. These findings confirm the diagnosis of autosomal recessive polycystic disease.

Figure 131-8. Ultrasonographic appearance of the kidneys in neonates with autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD) can be similar. A1 and A2, Newborn with ARPKD. Note the large size and hyperechoic, homogeneous appearance of the renal parenchyma. A2 is a cross-sectional cut of the baby's abdomen showing both kidneys to be quite large and occupying a large portion of the abdominal cavity. B1 and B2, Newborn with ADPKD. Again note the abnormal renal architecture and the hyperechoic appearance of the kidneys. The parenchyma consists of multiple tiny cysts, with some being slightly larger than others. (Courtesy Marta Hernanz-Schulman, MD.)

Figure 131-9. A1 and A2, Magnetic resonance images of an 8-month-old child with autosomal recessive polycystic kidney disease (ARPKD) demonstrating multiple renal cysts. A1, On T1-weighted image, fluid content of cysts appears dark. A2, On T2-weighted image, the fluid content appears white. B, Computed tomography scan of a child with ARPKD. Horizontal cuts showing contrast puddling in collecting ducts. C, Coronal cut. Note that the kidneys are enlarged and the enhancing renal parenchyma is effaced by nonenhancing cysts and represents the progression and normal history of the disorder. (A, Courtesy Walter Berdon, MD; B, courtesy Marta Hernanz-Schulman, MD.)

hydronephrosis (the kidneys are enlarged with hypoechogenic calyces), multicystic kidney (hypoechogenic cysts lie within a non-reniform mass that has very little parenchyma), sporadic glomerulocystic kidney disease (GCKD), bilateral mesoblastic nephroma, Wilms tumor, and bilateral renal vein thrombosis. If the diagnosis is in doubt, CT is valuable because it is more sensitive to inhomogeneity (and therefore to tumor) within abdominal masses.

Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD. Occasionally, a newborn with severe ADPKD can also have enlarged, homogeneously hyperechogenic kidneys. Age at onset can overlap, and typically, when ADPKD manifests at birth, cysts are apparent on the sonographic image. Macrocysts are rare in newborns with ARPKD but do increase in frequency as the child gets older, sometimes producing an appearance similar to that of the dominant disease.

Cysts less than 1 cm appear more often than large cysts (Avni et al, 2002) (Fig. 131-9). Hepatic fibrosis can rarely occur in patients with ADPKD, as can brain aneurysms with ARPKD (Cobben et al, 1990; Neumann et al, 1999). The correct diagnosis of ARPKD depends on the overall clinical data: a positive family history with a recessive mode of inheritance, a positive liver biopsy, and the lack of the extrarenal malformations often associated with other renal cystic diseases.

Treatment

No cure has been found for ARPKD. Respiratory care can ease or extend the child's life. Severely affected neonates may require unilateral or bilateral nephrectomy, because of respiratory and nutritional compromise. Patients who survive may require treatment for

hypertension, congestive heart failure, and renal and hepatic failure. Portal hypertension may be dealt with by decompressive procedures such as a splenorenal shunt. Esophageal varices may be managed, at least temporarily, by gastric section and reanastomosis. Endoscopic sclerotherapy is widely used in pediatric and adult patients with bleeding varices. Hemodialysis and renal transplantation must eventually be considered in many patients.

KEY POINTS: AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

- ARPKD is secondary to a mutation of the *PKHD1* gene on chromosome 6.
- The severe form manifests in utero or in infancy; milder cases can manifest later in childhood and rarely up to age 20.
- All affected individuals have some degree of congenital hepatic fibrosis.
- When it manifests early, it is associated most often with very large kidneys that are homogeneously hyperechogenic.
- Discrete cysts appear more often as the child gets older.
- RUS reveals bilateral, very enlarged, diffusely echogenic kidneys, and the increased echogenicity is a result of the presence of numerous microcysts (created by tightly compacted, dilated collecting ducts) that result in innumerable interfaces.
- Considerable overlap in clinical presentation and imaging findings can occur between ADPKD and ARPKD.

AUTOSOMAL DOMINANT (ADULT) POLYCYSTIC KIDNEY DISEASE

ADPKD is by far the most common inheritable form of renal cystic disease, with an incidence of approximately 1 in 400 to 1000 live births (Iglesias et al, 1983; Grantham, 1996). It is an important cause of renal failure, accounting for 7% to 15% of patients who receive hemodialysis (Hildebrandt, 1995; Grantham, 1996; Wilson, 2004). The trait theoretically has a 100% penetrance, and, on average, because it is transmitted in an autosomal dominant fashion, 50% of an affected individual's offspring will likewise be affected. Although a positive family history is one of the major criteria for the diagnosis of ADPKD, 10% of cases occur sporadically. Ninety-six percent of affected persons will manifest the disease clinically by age 90 years (Gabow, 1991).

Although most cases are identified between the fourth and fifth decades of life, the condition has been reported in newborns and infants (Proesmans et al, 1982). All affected individuals manifest the disease (although not necessarily symptomatically) if they live long enough, but renal failure is seldom seen before the age of 40 years, unless the disease manifests during infancy, in which case it is much more aggressive.

A number of associated anomalies are common, including cysts of the liver, pancreas, spleen, and lungs; aneurysms of the circle of Willis (berry aneurysms); colonic diverticula; aortic aneurysms; and mitral valve prolapse (Table 131-2).

Genetics

There are two major genetic forms of ADPKD caused by mutation in the genes *PDK1* and *PDK2* (Reeders et al, 1985; Breuning et al, 1987; Ryyanen et al, 1987; Piek et al, 1989). *PDK1* has been localized to the short arm of chromosome 16, with its gene product being polycystin-1. Mutations in the *PDK1* gene account for 85% of ADPKD cases. These patients typically have a more rapidly progressive form of the disease, with cysts usually developing by the age of 20 years (64% of children have cysts by the age of 10 years and 90% by the age of 20 years) and ESRD occurring in their 50s (Chakraborty and McHugh, 2005). The *PKD2* gene

TABLE 131-2 Comparison of Autosomal Recessive and Autosomal Dominant Polycystic Kidney Disease

	AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE	AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE
Gene defect	Chromosome 6	Chromosome 4 and 16
Incidence	1:5000-40,000	1:500-1100
Usual age at clinical presentation	Perinatal	Third to fifth decades
Typical ultrasonographic appearance of kidneys	Symmetrically enlarged, homogeneous, hyperechogenic	Large, cystic kidneys, sometimes asymmetrical
Histology	Collecting duct ectasia; cysts derived principally from collecting duct	Microcysts and macrocysts derived from the entire nephron
Liver	Always with congenital hepatic fibrosis but of varying severity	Cysts, mostly in adults
Other organ system(s) involvement	None	Intracranial (berry) aneurysms, colonic diverticuli; mitral valve prolapse; cysts of other organs (seminal vesicle, arachnoid membrane, pancreas)

has been mapped to the long arm of chromosome 4 and it encodes the protein polycystin-2. *PDK2* mutations account for about 15% of ADPKD cases, and in these patients, the disease progresses more slowly. ESRD usually does not occur until these patients are in their 70s (Hateboer et al, 1999). The presence of a third locus (*PKD3*) is now accepted as the cause of disease in a very small percentage of patients who have been found to have neither a *PKD1* nor a *PKD2* gene defect (Dauost et al, 1993). When either the *PKD1* or the *PKD2* gene is abnormal, cystic kidneys can develop. Because defects of *PKD1* and *PKD2* manifest similarly, it has been suggested that the gene product of each is involved in the same pathway and that an abnormality of either product results in similar manifestations of the disease (Qian et al, 1996).

Every cell of the nephron and collecting duct has the *PDK1* or *PDK2* mutation; however, only 1% to 2% of these glomerular units are affected by cyst formation. Only those nephrons that undergo a disruption of a second allele undergo cystic enlargement. This is the "second hit" of the Knudson theory, which has been proposed to explain the focal nature of the cysts (Knudson, 1971). In this model, a mutated *PKD1* (or *PKD2*) gene is inherited from one parent, and a wild-type gene is inherited from the unaffected parent. During the lifetime of the individual, the wild-type gene undergoes a somatic mutation and becomes inactivated. Loss of heterozygosity caused by somatic mutations of the *PKD1* and *PKD2* genes has been identified in the cells lining the cysts in both the kidney and liver (Qian et al, 1996; Watnick et al, 1998). The phenomenon of

genetic anticipation is seen as well; it manifests with progressively earlier presentation and increased severity in subsequent generations of patients with ADPKD (Fick et al, 1994; Zerres et al, 1994). Genetic testing for *PDK1* and *PDK2* is commercially available through polymerase chain reaction amplification and direct DNA sequencing.

Occasionally, the classic ADPKD phenotype is seen in conjunction with tuberous sclerosis. This association is a classic example of a “contiguous gene syndrome,” which is a disorder caused by deletion of multiple gene loci that are adjacent to one another. Contiguous gene syndromes are characterized by multiple, apparently unrelated, clinical features caused by deletion of the multiple adjacent genes. Owing to the fact that the *PDK1* gene is immediately adjacent to the *TSC2* gene (the most important gene in tuberous sclerosis) on chromosome 16, large deletions in this area can involve both the *PDK1* and *TSC2* genes. Thus these patients have the classic features of tuberous sclerosis in addition to the renal cystic phenotype of ADPKD.

Pathogenesis

The *PDK1* and *PDK2* proteins, polycystin-1 (PC1) and polycystin-2 (PC2), are transmembrane proteins that in all likelihood form a functional complex. When working properly, PC1 and PC2 inhibit cell proliferation by several pathways. Polycystin-1 functions as a mechanoreceptor located on the primary cilium of renal tubular cells. These cilia project from the surface of the cell into the lumen of the ducts and tubules. Mutations that block the assembly of these cilia are known to cause many cystic diseases of the kidney. The products of the *ADPKD*, *ARPKD*, and *nephronophthisis* (NPH) genes are at least partially localized to these primary cilia. Polycystin-1 is linked to polycystin-2, which contains a calcium (Ca^{2+}) channel. When the mechanoreceptor of PC1 is stimulated by calcium-containing urine flowing through the tubule, the calcium channel of PC2 opens and calcium enters the cell (Nauli et al, 2003; Braun, 2009). This process regulates the proliferative state of the renal tubular cells through a variety of signaling pathways (e.g., cAMP, extracellularly regulated kinase [ERK], mammalian target of rapamycin [mTOR]). The cilia likely serve as organization centers for this signal transduction (Pazour, 2004).

In ADPKD, the polycystins do not function properly, and these proliferative pathways are unopposed and cyst formation occurs to varying degrees.

Increased levels of cAMP have been noted in multiple animal models of ADPKD, and biochemical processes that alter cAMP appear to affect the presence and size of renal cysts. For example, cAMP is broken down by phosphodiesterases. Caffeine and methylxanthine products, such as theophylline, interfere with phosphodiesterase activity, raise cAMP in epithelial cell cultures from patients with ADPKD, and increase cyst formation in canine kidney cell cultures (Mangoo-Karim et al, 1989; Belibi et al, 2002). The abnormal response to cAMP is directly linked to alterations in Ca^{2+} channel activity and results in the abnormal response of cyst-derived cells. This has also been shown to be regulated by cAMP stimulation of the mitogen-activated protein kinase/extracellularly regulated kinase (MAPK/ERK) signaling pathways, which leads to abnormal cellular proliferation of the PKD renal epithelial cells.

Upregulation of the vasopressin V_2 receptor has also been shown to increase cAMP levels. In genetically produced polycystic animals, two antagonists of the vasopressin V_2 receptor (VPV2R), OPC31260 and OPC41061 (tolvaptan), decreased cAMP and ERK, prevented or reduced renal cysts, and preserved renal function (Gattone et al, 2003; Wang et al, 2005). Not surprisingly, simply increasing water intake decreases vasopressin production and the development of PKD in rats (Nagao et al, 2006). Polycystic kidney (PCK) animals with no vasopressin activity had virtually no cAMP or renal cysts, whereas animals with increasing amounts of vasopressin had progressively larger kidneys with more numerous cysts. Administration of synthetic vasopressin to PCK rats that totally lacked vasopressin re-created the full cystic disease (Wang et al, 2008; Braun, 2009). Finally, the absence of polycystin permits excessive kinase

activity in the mTOR pathway and the development of renal cysts (Shillingford et al, 2006). The mTOR system can be blocked by rapamycin, which has been shown to slow PKD progression in rats (Wahl et al, 2006).

Clinical Features

Phenotypes associated with ADPKD are highly variable in penetrance. This variability related to the severity of renal disease can range from fetal demise and neonatal death to adequate renal function into old age. Characteristics of the associated liver disease and extrarenal manifestations can also be quite variable. *PDK1* and *PDK2* gene mutations are obviously critical, but intrafamilial variability also indicates that genetic background and environmental factors can also affect ultimate clinical expression of the disease (Rossetti and Harris, 2007). Now that the families of ADPKD patients are being screened by ultrasonography, large numbers of asymptomatic children with renal cysts are being identified before full-blown disease develops. Bilateral renal involvement is the usual presentation, but 17% of cases are asynchronous or asymmetrical, especially in children. These extreme forms of asymmetry are referred to as *unilateral ADPKD*, with the involvement in the contralateral kidney becoming apparent at a much older age (Strand et al, 1989; Bisceglia et al, 2006).

Typically, signs or symptoms first occur between the ages of 30 and 50 years (Glassberg et al, 1981). These include microscopic and gross hematuria, flank pain, gastrointestinal symptoms (perhaps secondary to renomegaly or associated colonic diverticula), renal colic (secondary either to clots or stones), and hypertension. Microscopic or gross hematuria is seen in 50% of patients, and in 19% to 35% it is the presenting sign (Milutinovic et al, 1984; Delaney et al, 1985; Zeier et al, 1988; Gabow et al, 1992). Because patients with ADPKD have increased renal mass, erythropoietin levels are increased, making anemia unusual even when ESRD is present (Gabow, 1993).

Pain (flank and/or abdominal) is the most common presenting symptom in adults. This results from a number of possible factors: mass effect (cysts impinging on abdominal wall or neighboring organs), bleeding into the cysts, urinary tract infection (including infected cysts), and nephrolithiasis. Twenty percent to 30% of patients with ADPKD develop stones (Fick et al, 1994), and these are treated by conservative means if possible (i.e., urine alkalization, spontaneous stone passage, extracorporeal shock wave lithotripsy). Uric acid stones and calcium oxalate stones are equally prevalent. The finding of hydronephrosis, which helps make the diagnosis of stones, may not be as useful in ADPKD patients because of the number of cysts camouflaging the findings (Choyke et al, 1995). Urinary tract infections are more frequent in female patients. Cyst aspiration for both diagnostic and therapeutic reasons should be considered in the setting of suspected cyst infection.

As BP screening has become more widespread, hypertension has become a very common form of presentation (Zeier et al, 1988). Hypertension is present in roughly 50% of patients 20 to 35 years old having ADPKD with normal renal function. Virtually 100% of patients with ESRD have hypertension (Kelleher et al, 2004). The hypertension seems to be renin mediated, secondary to stretching of the intrarenal vessels around cysts, causing distal ischemia (Gabow, 1993). Diagnosis and treatment of this hypertension is critical to slow the progression of renal failure, as well as to decrease morbidity and mortality from heart disease and cerebral aneurysms.

The development of renal failure is highly variable. Renal function is usually maintained, despite increasingly rapid cyst growth, until the fourth to sixth decade of life. Risk factors for earlier onset of ESRD include *PKD1* gene mutation, male gender, first episode of hematuria before age 30 years, onset of hypertension before age 35 years, hyperlipidemia, and sickle cell trait (Yium et al, 1994; Johnson and Gabow, 1997). There is a strong relationship between the decline in renal function and the size of the kidneys and cyst volumes. As the cysts, and thus the kidneys, become

larger, renal function declines proportionately (Gabow et al, 1990a). Hypertension and vascular remodeling secondary to cyst expansion also contribute to progressive renal failure.

Extrarenal Manifestations

Hepatic cysts, usually identified incidentally by ultrasonography, are the most common extrarenal manifestation of ADPKD. These cysts are associated with *PKD1* and non-*PKD1* genotypes. They are rare in children, and their frequency increases with age. They are present in virtually all ADPKD patients by the age of 50 years (Bae et al, 2006). Hepatic cysts are more prevalent and their size greater in females (Fick et al, 1994). Several studies have shown an estrogen effect on hepatic cyst growth (Gabow et al, 1990b; Sherstha et al, 1997). Hepatic cysts are usually asymptomatic but can occasionally cause symptoms owing to mass effect or from complicating infection or hemorrhage. In rare instances, enlargement of hepatic cysts leads to portal hypertension and bleeding esophageal varices (Campbell et al, 1958). When secondary portal hypertension appears, differentiating ADPKD from ARPKD can be difficult. In ARPKD, portal hypertension is seen much more frequently and is always secondary to congenital hepatic fibrosis. However, congenital hepatic fibrosis, on very rare occasions, may accompany ADPKD as well, particularly when the diagnosis is made perinatally.

Intracranial aneurysms (ICAs)—predominately aneurysms of the circle of Willis (berry aneurysm)—occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages (Hartnett and Bennett, 1976; Grantham, 1979; Wakabayashi et al, 1983; Sedman and Gabow, 1984; Ryu, 1990). The most common symptom of subarachnoid hemorrhage is the sudden onset of a severe headache, frequently associated with nausea and vomiting. When this occurs, immediate medical evaluation is obviously imperative. Morbidity and mortality from these aneurysms are strongly influenced by positive family history and the *PDK1* genotype. Now, with MRI, even small berry aneurysms can be detected. These aneurysms, when diagnosed, average only 6.1 mm. Although small aneurysms (1 cm) have a lower risk of rupture, patients with small aneurysms have a greater risk of rupture when there is a positive family history of ruptured ICAs or the presence of ADPKD (Huston et al, 1993). Control of hypertension is critical to minimize the risk of aneurysm rupture. In some patients with ADPKD, hemorrhage follows the rupture of intracerebral arteries, which is the usual type of intracranial hemorrhage seen in patients with hypertension who do not have ADPKD.

Cysts may also occur in the seminal vesicles (40%), arachnoid membrane (8%), and pancreas (5%). Seminal vesicle cysts rarely cause infertility; however, many of these men may have problems with sperm motility. Arachnoid membrane and pancreatic cysts are typically asymptomatic. Other abnormalities associated with ADPKD are mitral valve prolapse and colonic diverticulosis (Scheff et al, 1980; Hossack et al, 1986; Kupin et al, 1987). Patients who have diverticulosis are more likely to have hepatic cysts and symptomatic berry aneurysms (Kupin et al, 1987).

Association with Renal Cell Carcinoma

The incidence of renal adenomas is almost as high in ADPKD as in ARCD associated with ESRD (i.e., one in four to five patients). However, whereas ESRD is associated with an increased incidence of RCC, especially when associated with ARCD (three to six times the incidence seen in the general population), the incidence of RCC in patients with ADPKD is no higher than that in the general population. However, there are certain findings considered typical of a predisposition to RCC that are seen more frequently in patients with ADPKD than in the general population. For example, RCC in ADPKD is often diagnosed at a younger age, is more often concurrently bilateral (12% vs. 1% to 5% in the general population), multicentric (28% vs. 6%), and

sarcomatoid in type (33% vs. 1% to 5%) (Keith et al, 1994). The diagnosis of RCC in the context of ADPKD can be quite difficult, because tumor may be masked by the complex cystic appearance of the kidney. In addition, cystic hemorrhage, degenerating blood clots, proteinaceous debris, and infection can also complicate the diagnosis.

Histopathology

ADPKD kidneys typically maintain their reniform shape, and their size can range from minimally enlarged in early disease to massive enlargement in more advanced disease. Both kidneys are usually equally affected, and the cysts range from a few millimeters to a few centimeters in diameter and appear diffusely throughout the cortex and medulla with communications at various points along the nephron (Kissane, 1974). The cysts appear to begin as focal tubular outpouchings, and as they enlarge they usually become detached from their tubule of origin. The first pathologic finding in fetuses is focal tubular dilation, which may occur anywhere along the nephron (Choyke et al, 1995) (Fig. 131-10).

Epithelial hyperplasia or even adenoma formation in the cyst wall is common, and the basement membrane of the wall is thickened. Arteriosclerosis is present in more than 70% of patients with preterminal or terminal renal failure, and interstitial fibrosis, with or without infiltrates, is common (Zeier et al, 1988). This fibrosis may be secondary to infection or to an inflammatory reaction set off by spontaneously rupturing cysts.

Up to 90% of adults with ADPKD have cysts of the liver (Bae et al, 2006). These cysts are lined by a single layer of epithelium resembling that of the biliary tract and contain fluid that resembles the bile salt-independent fraction of the bile. The electrolyte composition and osmolality are similar to those of serum, whereas the concentrations of phosphorus, cholesterol, and glucose are lower (Everson et al, 1990). They are derived by progressive proliferation and dilation of the biliary ductules and peribiliary glands and become detached as they grow so that macroscopic liver cysts usually do not communicate with the biliary system. Minimal to moderate dilation of the extrahepatic bile ducts is common (Torres and Grantham, 2008).

Evaluation

To make the diagnosis, it is important to have at least three generations of the patient's family history. Questions should be asked about renal disease, hypertension, and strokes. Patients and families should be counseled before any imaging or other testing is

Figure 131-10. Glomerular cysts with a pattern compatible with autosomal dominant polycystic kidney disease in early childhood (190 \times). (From Bernstein J, Gardner KD Jr. Cystic disease and dysplasia of the kidneys. In: Murphy WM, editor. Urological pathology. Philadelphia: Saunders; 1989. p. 483–524.)

undertaken. Genetic testing can be used when the imaging results are equivocal and when a definite diagnosis is required. Benefits of testing include making a diagnosis that may affect family planning, early detection and treatment of disease complications, and selection of genetically unaffected family members for living donor-related renal transplantation. Disadvantages to testing include discrimination in terms of insurability and employment associated with a positive diagnosis, as well as the psychological stress of impending organ failure.

Abdominal ultrasonography may reveal renal cysts (Fig. 131-11) as well as cysts in other organs. Ultrasonographic diagnostic criteria for individuals at 50% risk for the disease include at least two unilateral or bilateral cysts in individuals younger than 30 years of age, two cysts in each kidney in individuals 30 to 59 years of age, and four cysts in each kidney in individuals 60 years of age or older (Ravine et al, 1994). The sensitivity of these criteria is nearly 100% for individuals 30 years or older and for younger individuals with *PKD1* mutations but only 67% for individuals with *PKD2* mutations younger than 30 years (Nicolau et al, 1999). When there is no family history to support a diagnosis of ADPKD, a presumptive diagnosis can be made if bilateral renal cysts are present and two or more of the following symptoms are present as well: bilateral renal enlargement, three or more hepatic cysts, cerebral artery aneurysm, and a solitary cyst of the arachnoid, pineal gland, pancreas, or spleen (Grantham, 1993).

CT or MRI (or both) may be helpful in some cases and often is superior to ultrasonography for detecting cysts in organs other than the kidney (Fig. 131-12A). CT is helpful in making the diagnosis of hemorrhage within a cyst. More acute hemorrhage has a higher density (50 to 90 Hounsfield units [HU]) than old hemorrhage (Choyke et al, 1995). MRI also may be helpful, particularly in patients with compromised renal function, because no contrast agent is needed (Fig. 131-12B).

When ADPKD manifests in utero or in infancy, 50% of affected kidneys are large with identifiable macrocysts (Pretorius et al, 1987). However, the kidneys may appear identical to those seen

in ARPKD, having no apparent macrocysts and showing only enlargement and homogeneous hyperechoic features. In such situations, one must look for a parent with ADPKD to confirm the diagnosis. With time, cysts often larger than 1 cm will develop in most children (Avni et al, 2002).

Figure 131-11. Renal ultrasonogram of 20-year-old patient newly diagnosed with autosomal dominant polycystic kidney disease. Note the presence of multiple cysts in both kidneys. (Courtesy Marta Hernanz-Schulman, MD.)

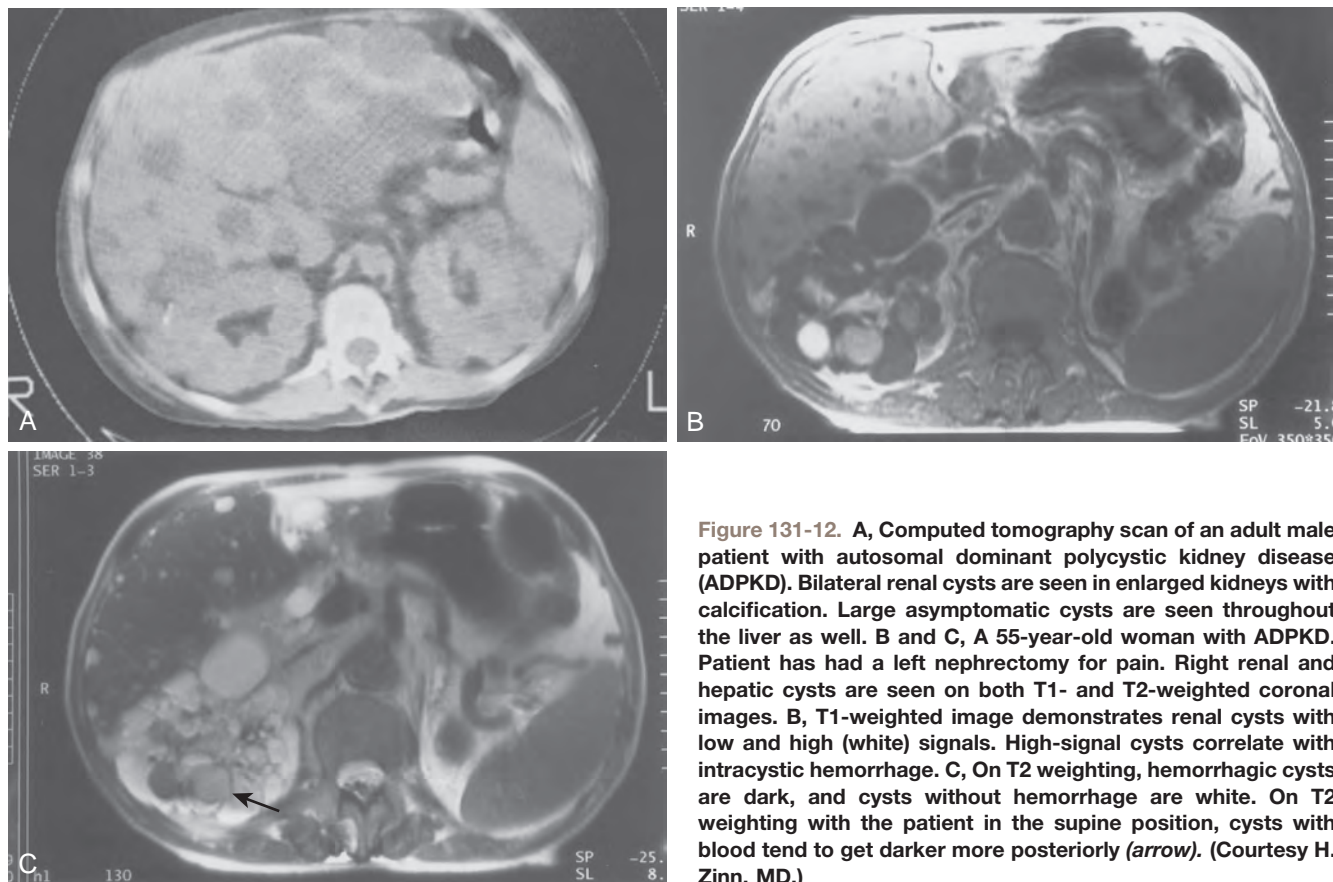

Figure 131-12. A, Computed tomography scan of an adult male patient with autosomal dominant polycystic kidney disease (ADPKD). Bilateral renal cysts are seen in enlarged kidneys with calcification. Large asymptomatic cysts are seen throughout the liver as well. B and C, A 55-year-old woman with ADPKD. Patient has had a left nephrectomy for pain. Right renal and hepatic cysts are seen on both T1- and T2-weighted coronal images. B, T1-weighted image demonstrates renal cysts with low and high (white) signals. High-signal cysts correlate with intracystic hemorrhage. C, On T2 weighting, hemorrhagic cysts are dark, and cysts without hemorrhage are white. On T2 weighting with the patient in the supine position, cysts with blood tend to get darker more posteriorly (arrow). (Courtesy H. Zinn, MD.)

Treatment and Prognosis

Current therapy is directed toward lessening the complications of ADPKD and delaying the onset of ESRD. There is no known cure at this time. More than 60% of patients with ADPKD who do not yet have renal impairment have hypertension (Gabow et al, 1984), which can worsen renal function, cause cardiac disease, and predispose the patient to intracranial hemorrhage. The complications of ADPKD can be reduced significantly by controlling the BP. There is no proven antihypertensive agent of choice; however, ACE inhibitors or angiotensin receptor antagonists would seem to be logical first-line choices. Not only does the hypertension associated with ADPKD appear to be renin mediated, but these drugs increase renal blood flow, have minimal side effects, and may have renoprotective properties beyond BP control. The optimum BP target is not clear. Ongoing studies will determine whether a low BP target is more protective of renal function than a standard BP target (<130/80) and whether combination drug therapy is more advantageous than single-drug therapy.

Chronic pain must be evaluated and entities such as infection, stone, and tumor treated accordingly. The use of chronic nephrotoxic analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs]) must be avoided. The use of narcotic analgesics should be limited to acute pain episodes, because patient dependence on narcotics is a significant risk in this patient population. When conservative measures fail, surgical management must be considered. Ultrasonography- or CT-guided cyst aspiration is a straightforward procedure and may be both diagnostic and therapeutic. Surgical unroofing of multiple or very large cysts can potentially alleviate symptoms of pain and can be performed either laparoscopically or through open flank or dorsal lumbar incisions (Elzinga et al, 1992; Lee and Lee, 2003; Lee and Clayman, 2004). The effect of laparoscopic unroofing in those patients with hypertension was quite variable. Surgical intervention appears only to improve symptomatology and does not appear to either accelerate the decline of renal function or preserve declining renal function. Nephrectomy is indicated for symptomatic patients with ESRD.

Upper urinary tract infections are common in patients with ADPKD, especially women, and must be treated appropriately. If a patient with suspected pyelonephritis does not respond to an appropriate antibiotic, one must consider whether the infection may be present in a noncommunicating cyst (Gabow, 1993). Actual cyst infections can be quite challenging to treat owing to poor cyst penetration of many antibiotics. Lipophilic antibiotics, such as trimethoprim-sulfamethoxazole, chloramphenicol, and fluoroquinolones, are the best choices (Schwab et al, 1987; Bennett et al, 1990). If appropriate antibiotic therapy fails, percutaneous or surgical drainage of infected cysts may be required. Complicating factors, such as urinary tract obstruction, renal or perinephric abscess, or urolithiasis, must be excluded.

Screening for asymptomatic berry aneurysms is not currently recommended unless the patient has a family history of aneurysm or subarachnoid hemorrhage, previous aneurysm rupture, need for screening in preparation for major elective surgery, high-risk occupation (e.g., airline pilot), or a high anxiety level over the possibility of ICA (Pirson et al, 2002). CT and magnetic resonance angiography are the imaging studies of choice, although the former requires intravenous contrast. Aneurysm rupture occurs most often in people with larger aneurysms and/or poorly controlled high BP. Screening of low-risk patients is not recommended because aneurysms are rare in this group, and most aneurysms that are found have a low risk of rupture. Conservative management is usually recommended for ADPKD patients with small (<7 mm) aneurysms detected by presymptomatic screening. Aneurysms that are larger than 7 to 10 mm have a higher risk of rupture (up to 2% per year for larger aneurysms). Cerebral aneurysms of this size and those that cause symptoms may be corrected with open surgical clipping or with endovascular procedures, placing a coil within the aneurysm. Smaller aneurysms that do not cause symptoms are much less likely to rupture and are not routinely corrected, except in patients with a history of a bleeding aneurysm.

Emerging Therapeutics

Changing the natural course of the disease by altering the course of cyst growth has received the most attention in recent years. The HALT PKD study is the largest treatment study ever performed on patients with PKD, and the National Institutes of Health (NIH) extended the study because of the valuable information being obtained. This study examined the role of BP control versus the impact of specific medications on the course of the disease and assessed whether combination ACE inhibitor (lisinopril) and angiotensin receptor blocker (ARB; telmisartan) therapy is more effective in slowing cyst progression than ACE inhibition alone. The study was completed in June 2014, and in a recent report by Schrier and colleagues (2014) showed that in early ADPKD, the combination of lisinopril and telmisartan did not significantly alter the rate of increase in total kidney volume. As compared with standard blood-pressure control (120-130/70-80), rigorous blood-pressure control (95-110/60-75) was associated with a slower increase in total kidney volume, no overall change in the estimated GFR, a greater decline in the left-ventricular-mass index, and greater reduction in urinary albumin excretion (Schrier et al, 2014). From this study, the investigators also hope to learn how to predict when renal insufficiency will occur in individual patients (Steinman, 2011).

Approaches have also been undertaken to reduce the levels of cAMP in the kidneys of ADPKD patients. A recent phase III trial showed that compared with placebo, tolvaptan, a selective vasopressin V₂-receptor antagonist, slowed the increase in total kidney volume and the decline in renal function over a 3-year period in these patients. It was, however, associated with a relatively high discontinuation rate as a result of adverse events, such as increased aquaresis (thirst, polyuria, nocturia, and polydipsia as a result of the excretion of electrolyte-free water) and liver function abnormalities. Serious adverse events associated with chest pain and headache were also slightly more frequent in the tolvaptan group (Torres, 2012).

Somatostatin, known to inhibit vasopressin-induced cAMP, has also been tested in humans and has shown substantial retardation of the increase in kidney volume (Chapman, 2007). Two studies have evaluated the efficacy of blocking mTOR with rapamycin and have shown a significant reduction in kidney cyst burden (Tao et al, 2005; Wahl et al, 2006). Other drugs shown to be effective in pre-clinical trials and of potential value for the treatment of human PKD include ErbB1 (epidermal growth factor receptor) and ErbB2 tyrosine kinase inhibitors, Src kinase inhibitors, MEK inhibitors, and cyclin-dependent kinase inhibitors. These drugs, which have been developed for the treatment of neoplastic diseases, may also be considered for the treatment of PKD (Sweeney et al, 2000; Bukanov et al, 2006; Omori et al, 2006; Wilson et al, 2006; Brenner, 2008).

JUVENILE NEPHRONOPHTHISIS AND MEDULLARY CYSTIC DISEASE COMPLEX

Juvenile NPH (first described by Fanconi and colleagues in 1951) and medullary cystic kidney disease (MCKD) (first reported by Smith and Graham in 1945) describe a group of genetic (inheritable) disorders with both similar and unique characteristics. Similarities include the gross and histopathologic appearance of the kidneys, with the hallmark being interstitial fibrosis. Distinguishing features are the mode of inheritance, the age of onset of ESRD, and the type of extrarenal organ involvement. Juvenile NPH is the more common condition and is responsible for 10% to 20% of cases of renal failure occurring in children and occurs in 1% to 5% of patients undergoing dialysis or transplantation (Cantani et al, 1986) (see Table 131-1).

Genetics

Although either condition can occur sporadically, juvenile NPH usually is inherited as an autosomal recessive trait. It is genetically heterogeneous, and 13 responsible genes have been identified

KEY POINTS: AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

- ADPKD is the most common inheritable form of renal cystic disease.
- ADPKD most often becomes clinically apparent after age 30 years but may manifest at any age, including in utero.
- Ninety-nine percent of affected individuals have a mutation either of the *PKD1* gene on chromosome 16 or, less often, of the *PKD2* gene on chromosome 4.
- The protein products of *PKD1* and *PKD2* are PC1 and PC2, and they inhibit cell proliferation through several pathways.
- Cysts can be identified sonographically before age 20 years in almost all affected individuals.
- ADPKD is associated with a high incidence of liver cysts that increases with age.
- Signs or symptoms first occur between the ages of 30 and 50 years and include hematuria, flank pain, gastrointestinal symptoms, renal colic, and hypertension.
- Hepatic cysts occur in virtually all patients with ADPKD by the age of 50 years and are rarely symptomatic.
- ICAs of the circle of Willis (berry aneurysm) occur in 10% to 30% of patients, and approximately 9% of these patients die because of subarachnoid hemorrhages.
- The incidence of RCC in ADPKD patients is no higher than that of the general population.
- Tight BP control, the use of ACE inhibitors and/or ARB BP medication, and the possible use of tolvaptan are the most current treatment options.

for various forms of NPH (Hildebrandt et al, 1997; Saunier et al, 1997; Olbrich et al, 2003; Otto et al, 2003; Mollet et al, 2005; Otto et al, 2005; Sayer et al, 2006; Loftus, 2013). The *NPHP1* gene encodes nephrocystin; *NPHP2/INVS*, inversin; *NPHP3*, nephrocystin-3; *NPHP4*, nephrocystin-4/nephroretinin; *NPHP5/IQCB1*, nephrocystin-5; and *NPHP6/CEP290*, nephrocystin-6. *NPHP1* mutations are found in approximately one half of the patients with NPH. The majority of patients are homozygous for an *NPHP1* deletion (Konrad et al, 1996). *NPHP1*, *NPHP4*, *NPHP5*, and *NPHP6* mutations may be associated with the Senior-Loken syndrome (a combination of NPH and retinitis pigmentosa).

MCKD usually is inherited in an autosomal dominant fashion (50% of all offspring will have the disease) and is caused by mutations in either the *MCKD1* or *MCKD2* gene. The *UMOD* gene encodes for uromodulin, the most abundant protein found in normal human urine. Mutations in this gene can also lead to MCKD type 2 (Loftus, 2013). Because patients with either condition theoretically can be fertile in their early childbearing years, the risk of transmitting the condition to offspring must be acknowledged: 1% for juvenile NPH and 50% for MCKD (Neumann et al, 1997).

Clinical Features

Juvenile NPH and MCKD both cause polydipsia and polyuria in more than 80% of patients, but not to the extent observed in patients with diabetes insipidus (Gardner and Evan, 1984; Cantani et al, 1986). The polyuria is caused by a renal tubular urinary concentrating defect that leads to salt wasting, and this process is resistant to vasopressin. Subsequently, a large dietary salt intake frequently is necessary. One major difference in the two entities is the presence of hypertension. There is no hypertension associated with juvenile NPH, whereas patients with MCKD can have significant hypertension. Rarer versions of NPH occur as well: infantile NPH (ESRD in patients 4 years of age or younger) results from a mutation in the *NPHP2/INVS* gene, and adolescent NPH (ESRD variable, occurring in patients ranging from 3 to 13 years old) results from a mutation in the *NPHP3* gene.

Renal failure usually ensues 5 to 10 years after initial presentation (Cantani et al, 1986). Another important difference between

the two entities is that renal failure develops in patients with NPH at a mean age of 13 years and almost always before 25 years (Neumann et al, 1997). MCKD is a milder disease when it manifests in early adulthood, but it will manifest in all patients by 50 years of age (Bernstein and Gardner, 1979). ESRD in patients with MCKD most often develops in the third or fourth decade. MCKD type 1 manifests as slowly progressive chronic renal disease. There is minimal proteinuria and hematuria, and hypertension and hyperuricemia become more common as the renal disease progresses. Hyperuricemia is characteristic of MCKD2, and gout is a common presentation in teenage males. Proteinuria is minimal (Bleyer, 2003; Loftus, 2013).

Twenty percent of juvenile NPH families have extrarenal manifestations, whereas MCKD usually affects only the kidneys (Neumann et al, 1997). Sixteen percent of patients with juvenile NPH have associated retinitis pigmentosa (Hildebrandt et al, 1993). When the two entities coexist, the condition is referred to as renal-retinal or Senior-Loken syndrome. More rarely, other conditions can also be present, such as skeletal abnormalities; hepatic fibrosis; Bardet-Biedl syndrome (combination of obesity, mental retardation, polydactyly, retinitis pigmentosa, and hypogenitalism); ocular motor apraxia (Cogan syndrome); and other neurologic defects varying from subtle cerebellar involvement to clear Joubert syndrome (JS) phenotypes, peripheral dysostosis (cone-shaped epiphyses), or truncal cerebellar ataxia (Hildebrandt and Orman, 2001).

Pathologically, NPH and MCKD are similar. Grossly, the kidneys are small to normal in size with multiple cysts at the corticomedullary junction. Histologically, there is a characteristic triad present that includes (1) irregular thickening and disintegration of the tubular basement membrane, (2) marked tubular atrophy with cyst development, and (3) interstitial cell infiltration with fibrosis.

Evaluation

Diagnosis of NPH and MCKD can be difficult early in the onset because of the relative vagueness and nonspecificity of symptoms; thus a high index of suspicion is required. Excretory urography and ultrasonography frequently fail to detect cysts because they are small (Chang and Udupa, 1989; Ala-Mello et al, 1998). Excretory urography may show inhomogeneous streaking in the medulla as a result of accumulation of contrast material in the collecting ducts. Ultrasonography may show smaller-than-normal kidneys in juvenile NPH. Cysts may be seen on imaging studies if they are large enough (Rosenfeld et al, 1977), but, early in the disease, cysts are rarely visible. The parenchyma may also appear hyperechogenic secondary to tubulointerstitial fibrosis (Resnick and Hartman,

Figure 131-13. Features of medullary cystic kidney disease. Ultrasonogram demonstrating corticomedullary cysts, some of which are indicated by arrows. The hyperechogenicity is secondary to the tubulointerstitial fibrosis. (From Simms RJ, Eley L, Sayer JA. Nephropthisis. *Eur J Hum Gen* 2009;17:406-16.)

1990) (Fig. 131-13). Contrast-enhanced CT and MRI scans are more sensitive for detecting small corticomedullary and medullary cysts, but failure to detect cysts does not exclude the diagnosis.

Treatment

The treatment of NPH is supportive. Because of the tendency for sodium wasting, volume contraction, and renal azotemia, sodium replacement is indicated early in the course of the disease, and unnecessary sodium restriction or use of diuretics should be avoided. Later, dialysis and transplantation must be considered. Allografts apparently are not susceptible to the same process that destroyed the native kidney, because there is no evidence of serum antibodies to the basement membrane or other renal structural proteins (Cantani et al, 1986; Cohen and Hoyer, 1986). If kidneys from siblings are considered for transplant surgery, precautions should be taken to obtain them only from unaffected, older relatives, who should be subjected to meticulous diagnostic evaluation.

KEY POINTS: JUVENILE NEPHRONOPHTHISIS AND MEDULLARY CYSTIC DISEASE COMPLEX

- Juvenile NPH, an autosomal recessive disease, is responsible for 10% to 20% of cases of renal failure in children and leads to early ESRD (early teens).
- MCKD, an autosomal dominant disease, manifests in early adulthood.
- Polyuria, polydipsia, and hypertension are clinical hallmarks of these disease entities.
- Both have almost identical histology, with severe interstitial nephritis; many patients demonstrate cysts at the corticomedullary junction.

OTHER INHERITABLE RENAL CYSTIC DISEASES (CONGENITAL NEPHROSIS)

Congenital nephrosis is predominantly of two types. The more common variety is referred to as *congenital nephrotic syndrome of the Finnish type* (CNF) (Norio, 1966; Lanning et al, 1989) and is recessive. The second type is referred to as *diffuse mesangial sclerosis* (DMS), and one third are familial (Habib and Bois, 1973; Habib et al, 1989). These conditions are associated with dilation of the proximal convoluted tubules, and the patients have profound proteinuria. In infants with CNF, proteinuria is present in the first urinalysis. Without dialysis, half of the patients die by the age of 6 months, and the rest die before their fourth birthday (Huttunen, 1976). In DMS, the onset of symptoms is variable, and the diagnosis is usually made by the age of 1 year. All children have terminal renal failure by the age of 3 years. Approximately one third of DMS cases are associated with Drash syndrome (nephrotic syndrome and Wilms tumor with or without male pseudohermaphroditism) (Habib et al, 1989). Interstitial fibrosis is present in both conditions but is more pronounced in DMS (Norio and Rapola, 1989). After the kidneys have failed, transplantation is curative. Neither type of disease responds to corticosteroids.

FAMILIAL HYPOPLASTIC GLOMERULOCYSTIC KIDNEY DISEASE (CORTICAL MICROCYSTIC DISEASE)

Cortical microcystic disease is an autosomal dominant disorder described in several families and has been called *hypoplastic glomerulocystic disease* (Rizzoni et al, 1982) and cortical microcystic disease (Melnick et al, 1984; Kaplan et al, 1989a). The diagnosis of familial hypoplastic glomerulocystic disease requires four features: (1) stable or progressive chronic renal failure, (2) small or normal-sized kidneys with irregular calyceal outlines and abnormal papillae, (3)

presence of the condition in two generations of a family, and (4) histologic evidence of glomerular cysts.

MULTIPLE MALFORMATION SYNDROMES WITH RENAL CYSTS

Renal cysts are a feature of several syndromes characterized by multiple malformations (see Table 131-1). Tuberous sclerosis and VHL disease are autosomal dominant disorders and are the ones most likely to be encountered by urologists. Meckel syndrome, Jeune asphyxiating thoracic dystrophy, and Zellweger cerebrohepato renal syndrome are some of the more common autosomal recessive syndromes. Many of these conditions involve glomerular cysts, and some have cystic dysplasia as a feature.

Tuberous Sclerosis Complex

Bourneville described tuberous sclerosis in 1880. It is usually an autosomal dominant neurocutaneous disorder with an incidence of up to 1 in 6000 individuals (Webb et al, 1991; O'Hagan et al, 1996). It is characterized by benign growths called *hamartomas*, which can develop in nearly every organ of the human body.

Classically, tuberous sclerosis has been described as the triad of Bourneville phakomatosis (epilepsy) (80% of patients), mental retardation (60% of patients), and adenoma sebaceum (facial angiofibromata) (75% of patients) (Lagos and Gomez, 1967; Pampiglioni and Moynahan, 1976). It is also associated with autism and other neurocognitive and behavioral disabilities (Kohrman, 2012). Adenoma sebaceum consists of firm, discrete, red or brown telangiectatic papules located in the nasolabial folds, chin, and cheeks. They usually appear after the age of 2 years, gradually become more prominent with time, and persist throughout life. An earlier skin lesion that is a white papule in the shape of an ash leaf is sometimes identified (Shepherd et al, 1991). An examination of the skin with ultraviolet light may reveal cutaneous lesions earlier and should be part of a diagnostic evaluation.

Definitive diagnosis, however, is no longer dependent on this triad but rather on the presence of certain major and minor clinical features (Roach et al, 1998). The diagnosis of tuberous sclerosis complex (TSC) requires two major features (renal angiomyolipoma [AML], facial angiofibromas or forehead plaques, nontraumatic ungual or periungual fibroma, three or more hypomelanotic macules, shagreen patch, multiple retinal nodular hamartomas, cortical tuber, subependymal nodule, subependymal giant cell astrocytoma, cardiac rhabdomyoma, lymphangioleiomyomatosis) or one major plus two minor features (multiple renal cysts, nonrenal hamartoma, hamartomatous rectal polyps, retinal achromic patch, cerebral white matter radial migration tracts, bone cysts, gingival fibromas, "confetti" skin lesions, multiple enamel pits).

The kidneys of these patients may be free of lesions (Stillwell et al, 1987) or may display cysts, AMLs, or both (Figs. 131-14 and 131-15).

Genetics

Although it is transmitted as an autosomal dominant trait in 25% to 40% of patients, in the remainder, tuberous sclerosis occurs either sporadically or as an example of the genetic condition with variable or incomplete penetrance. Because it is a heterogeneous genetic disorder with variable manifestations, it usually is referred to as *tuberous sclerosis complex*. It is caused by mutations in one of two genes. *TSC1* is located on chromosome 9 (9q34) and encodes the protein hamartin, and *TSC2* is on chromosome 16 (16p13) and encodes the protein tuberlin (Jones et al, 1999; Dabora et al, 2001; Sancak et al, 2005). Both of these genes are characterized as tumor suppressor genes, and the loss of function of either gene leads to hamartoma formation. Both hamartin and tuberlin function as a complex to inhibit the mTOR pathway. This pathway serves to modulate cell signaling pathways that are important in the regulation of cell growth and migration, as well as cell number and

Figure 131-14. A and B, Renal ultrasonogram of 13-year-old patient with tuberous sclerosis. Multiple hyperechoic lesions of varying size are visible, consistent with angiomyolipomas. (Courtesy Marta Hernanz-Schulman, MD.)

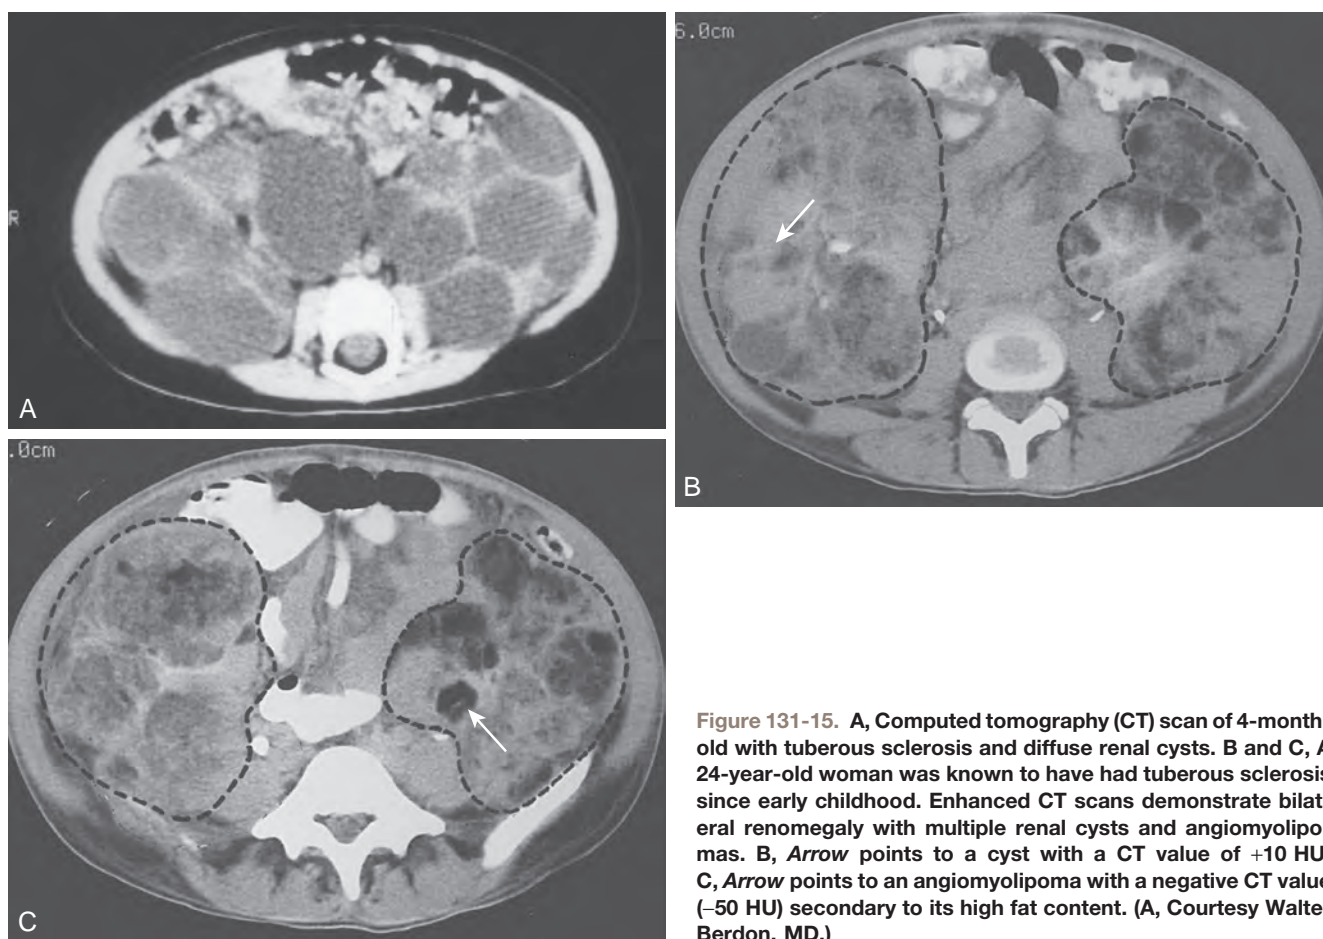

Figure 131-15. A, Computed tomography (CT) scan of 4-month-old with tuberous sclerosis and diffuse renal cysts. B and C, A 24-year-old woman was known to have had tuberous sclerosis since early childhood. Enhanced CT scans demonstrate bilateral renomegaly with multiple renal cysts and angiomyolipomas. B, Arrow points to a cyst with a CT value of +10 HU. C, Arrow points to an angiomyolipoma with a negative CT value (-50 HU) secondary to its high fat content. (A, Courtesy Walter Berdon, MD.)

organ size. Therefore a mutation of either gene will lead to similar clinical manifestations (Fig. 131-16).

Clinical Features

Renal involvement in TSC is second only to central nervous system abnormalities and includes predominately AML, renal cysts, and RCCs. AMLs are extremely common in TSC and are usually bilateral and multiple and affect both genders, whereas in the general

population they are uncommon, are usually single, and are found mainly in middle-aged women. Renal AMLs occur in 40% to 80% of patients with TSC (Chonko et al, 1974; Gomez, 1979). They are rarely identified before the age of 6 years but are common after age 10 years (Bernstein and Gardner, 1986). The primary risk of these lesions relates to their potential for hemorrhage or mass effect. Abdominal or flank mass and tenderness, hypertension, and renal insufficiency can also occur as a result of these lesions. By themselves, these lesions probably do not cause renal failure

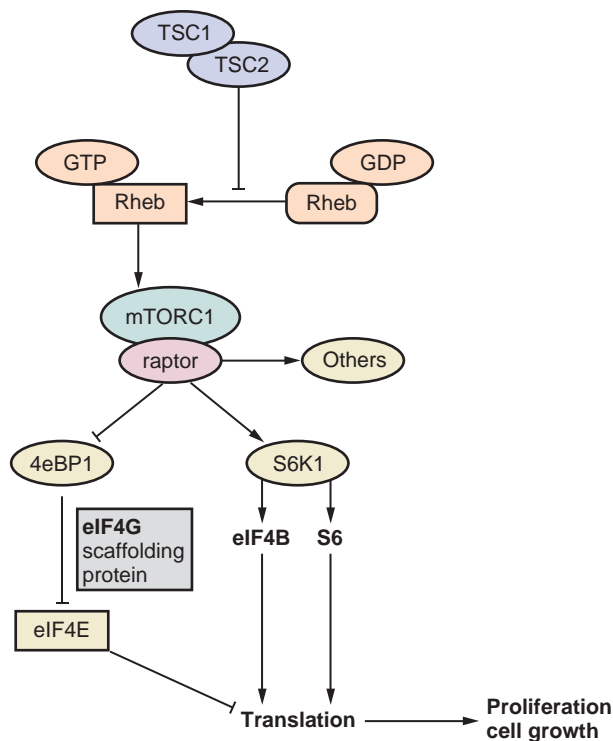

Figure 131-16. Features of signaling through the mammalian target of rapamycin complex 1 pathway (mTORC1) via the tuberous sclerosis 1/tuberous sclerosis 2 complex. 4EBP1, eukaryotic translation initiation factor 4E binding protein 1; eIF4B, eukaryotic translation initiation factor 4B; eIF4E, eukaryotic translation initiation factor 4E; eIF4G, eukaryotic translation initiation factor 4G; GDP, guanosine diphosphate; GTP, guanosine triphosphate; Rheb, Ras homolog enriched in the brain; S6, ribosomal protein S6; S6K1, ribosomal protein S6 kinase 1; TSC1, tuberous sclerosis complex 1 protein; TSC2, tuberous sclerosis complex 2 protein.

(Okada et al, 1982; Bernstein and Gardner, 1986). Also, belying their aggressive histologic appearance, which is characterized by pleomorphism and mitoses, no evidence of metastases has been presented.

Unlike AMLs, renal cysts may be present in the first year of life, and cystic disease may be the presenting manifestation of TSC. Renal cysts develop in approximately 20% of patients and most often manifest before 3 years of age; one third of children are younger than 1 year of age at presentation. Patients with large cysts or PKD may be identified by in utero ultrasonography or may demonstrate an abdominal mass and distended abdomen in the first year of life. Most patients with renal cysts do not develop any serious renal compromise, but when the disease is more widespread within the kidney and large cysts are present, renal failure may develop in the milder form with PKD. If any renal failure develops, it is uncommon before the fourth decade (Glazier et al, 1996).

TSC2 and PKD1 lie adjacent to each other in a tail-to-tail orientation on chromosome 16 at 16p13.3. Deletions inactivating both genes are associated with PCKs diagnosed during the first year of life or early childhood (TSC2/PKD1 contiguous gene syndrome) (Brook-Carter et al, 1994; Sampson et al, 1997). Therefore TSC should be considered in children with renal cysts and no family history of PKD. Rarely, TSC2/PKD1 contiguous gene syndrome can be diagnosed in adults (Martignoni et al, 2002). Patients with the contiguous gene syndrome usually reach ESRD at an earlier age than patients with ADPKD alone. Patients with TSC1 or TSC2 mutations without the contiguous gene syndrome also have an increased frequency of renal cysts. The combination of cystic kidneys and

AMLs has been said to be virtually pathognomonic for tuberous sclerosis.

Association with Renal Cell Carcinoma

The numerous reports of RCC in patients with tuberous sclerosis make it clear that this association is more than coincidental and may be as frequent as 2% (Bernstein and Gardner, 1986; Bernstein, 1993). However, the incidence of RCC is considerably less than that seen in VHL disease and ARCD of chronic renal failure. Compared with sporadic RCCs, there is a female predominance, earlier age of presentation, and increased bilaterality. Early detection is essential. RCC should be suspected in cases of enlarging lesions without demonstrable fat and in the presence of calcifications within the lesions.

Radiographic Evaluation

Sometimes both renal cysts and AMLs can be identified by ultrasonography in tuberous sclerosis, the former lesions being sonolucent and the latter having a fluffy, white appearance. When renal cysts are present without AMLs, the ultrasonographic appearance of the kidneys in tuberous sclerosis is very similar to that in ADPKD. Therefore it is not that unusual for a patient with cysts identified as typical of ADPKD to be diagnosed as having ADPKD, only to develop the stigmata of tuberous sclerosis a few years later. To help make the diagnosis, abdominal CT can be useful in demonstrating AMLs that may be present in the kidney or other organs (findings that are compatible with tuberous sclerosis) and in revealing cysts in other organs (compatible with ADPKD) (see Fig. 131-15). MRI or CT of the head may demonstrate the classic cranial calcifications associated with tubers or gliosis (Okada et al, 1982).

Treatment

Because more patients with tuberous sclerosis now survive their central nervous system lesions than in the past, the urologist is more likely to be asked to manage the renal problems (Stillwell et al, 1987). Shepherd and colleagues (1991) found that renal disease was the leading cause of death in these patients (11 of 40 deaths). Of these 11 patients, 2 died of metastatic RCC, 2 of massive hemorrhage associated with renal AMLs, and 6 of renal failure secondary to the cysts, AMLs, or both.

AMLs are benign lesions that usually are asymptomatic and do not require treatment. Large AMLs are more likely to bleed. van Baal and colleagues (1994) recommended careful monitoring of the size of AMLs and prophylactic embolization or surgical excision if they enlarge to greater than 4 cm. Annual surveillance with RUS or CT is necessary to assess for growth of the lesions and to detect the development of other complications. Renal-sparing surgery is indicated for symptoms such as pain and hemorrhage, growth of the lesions to the point at which they compromise renal function, and the inability to exclude RCC. Reports of hemorrhagic complications during pregnancy have led to the recommendation that patients with multiple or large AMLs be warned about the potential risk of pregnancy and estrogen administration.

Hypertension and renal failure must also be treated appropriately. Bilateral nephrectomy should be considered before transplantation owing to the risk of life-threatening hemorrhage and the development of RCC.

Finally, treatment in rodent models of TSC with rapamycin before the onset of disease reduces the development of renal tumors without affecting the number of precursor lesions (Kenerson et al, 2005). Clinical trials of the mTOR inhibitor rapamycin have demonstrated reduction in the size of tuberous sclerosis-associated renal, lung, and brain tumors. Sirolimus (rapamycin) and everolimus have demonstrated reduction in size of subependymal giant cell astrocytomas, reduction in seizure frequency, and inhibition of AML growth and even reduction of AML size in some reports (Kohrman, 2012). Larger-scale randomized controlled trials of mTOR inhibitors continue.

von Hippel-Lindau Disease

In 1904, Eugene von Hippel, a German ophthalmologist, first described retinal angiomas—angiomatic lesions of the retina that caused blindness in association with similar cerebellar tumors. One of his patients developed renal cancer, and this was reported in 1921. In 1926, Arvid Lindau, a Swedish pathologist, published a series about patients with retinal and cerebellar tumors, with four of his patients also having renal cysts and renal cancer. He was also the first to propose that these lesions had an inherited origin.

VHL disease is an autosomal dominant syndrome manifesting with cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney, and epididymis; epididymal cystadenoma; pheochromocytoma; and clear cell RCC. It is found in all ethnic groups, both sexes are affected, and it has an incidence ranging from 1 in 30,000 to 1 in 50,000 individuals. It has over 95% penetrance by the age of 65 years in affected individuals. It is grouped with the phakomatoses (Sturge-Weber-Krabbe syndrome, TSC, and neurofibromatosis), because they all have a common inheritance pattern and propensity for neoplasm.

Etiology

VHL disease is caused by a germline mutation in the tumor suppressor gene known as *VHL*, located on chromosome 3 (3p25) (Latif et al, 1993; Lesho, 1994; Kondo and Kaelin, 2001). A tumor suppressor gene is one in which both copies of the gene must be disabled for a cancer to develop. Seventy percent of patients will have a mutation of one *VHL* allele. As long as one copy of the *VHL* gene is producing functional VHL protein in each cell, tumors do not form. If a mutation occurs in the second copy of the *VHL* gene during a person's lifetime (another example of a second hit as proposed by Knudson's two-hit hypothesis (Knudson, 1971), the cell will have no working copies of the gene and will produce no functional VHL protein. A lack of this protein allows tumors characteristic of VHL syndrome to develop. The discovery and characterization of the *VHL* gene, and its role in cell regulation, is a prime example of how discoveries in the basic science arena can revolutionize treatment of human disease (Clark and Cookson, 2008).

The protein encoded by the *VHL* gene (pVHL) is a tumor suppressor and acts through multiple routes. It forms a complex of proteins that are involved with specific target proteins, typically hypoxia-inducible factors (HIFs), being "marked" for degradation. The most researched of these targets is hypoxia-inducible factor-1 α (HIF-1 α), a transcription factor that induces the expression of a number of angiogenesis-related factors (Czyzk-Krzeska and Meller, 2004). HIF1 α , when not suppressed, can stimulate the formation of hemangioblastomas and RCC. HIF targets specific genes that encode growth factors that seem to play a role in tumorigenesis, including platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), and vascular endothelial growth factor (VEGF), the last of which is particularly prominent in RCC. HIF1 α and pVHL are also involved in a transcriptional system that is a major regulator in oxygen homeostasis. HIF regulation in normoxia depends on VHL-mediated destruction. When the oxygen supply is reduced, the HIF pathway is activated. Together with activation of HIF in normoxia, VHL-deficient cells show a striking defect in extracellular matrix assembly. Thus altered oxygen tension in pathologic settings could have major effects on matrix behavior (Esteban et al, 2004). pVHL has also been shown to be a ciliary protein that controls ciliogenesis in kidney cells. Cilia play an important role in several biologic processes, including mechanosensation, photoperception, and osmosignaling. Loss of pVHL appears to impede the formation of cilia in renal cancer cells, whereas the expression of pVHL in VHL-negative renal cancer cells rescued the ciliogenesis defect (Schermer et al, 2006).

Clinical Features

The mean age at presentation is 35 to 40 years (Neumann et al, 1997). There is no sex preference for the disease or for RCC

development. Sporadic RCC in individuals without VHL disease occurs more often in males and usually after age 50 years. **Renal cysts, the most common and often earliest manifestation, are seen in 76% of patients (Levine et al, 1982).** The cysts are bilateral in 75% of affected persons and multifocal in 87% (Reichard et al, 1998). RCC occurs in approximately 50% of affected persons. The renal cysts, as well as the tumors, usually are asymptomatic, although large tumors may cause pain or a mass. Hematuria may occur after rupture of the tumor into the pelvicalyceal system. When cysts are present, typically they are large. Only rarely do images demonstrate ADPKD, and even less often do cysts cause renal failure.

Pheochromocytoma occurs in 10% to 17% of affected persons and appears to be confined to specific families (Horton et al, 1976; Levine et al, 1982). Patients may have seizures or dizziness secondary to hemangioblastomas of the central nervous system. **Cerebellar hemangioblastomas** usually become symptomatic between 15 and 40 years of age (Jennings and Gaines, 1988). These lesions are the most frequent, characteristic, and clinically specific tumors seen in VHL (Zbar et al, 1996; Shehata et al, 2008). Although benign tumors, they often result in major morbidity and mortality. They cause a mass effect because of their location, and, because of their vascular nature, they tend to rupture and bleed. **Retinal angiomas (hemangiomas)** frequently manifest early. Bleeding may cause blurred vision, retinal detachment, and blindness. Early diagnosis is important, because these tumors respond to laser therapy or cryotherapy. The pancreas is commonly involved with either cysts or true neoplasms. **Pancreatic cysts** can occur in up to 70% of patients with VHL but are usually asymptomatic and benign. Islet cell tumors occur in approximately 12% of VHL patients, and metastatic RCC of the pancreas is not unusual (Cheng et al, 1997; Kogire et al, 2000). Other clinical findings in patients with VHL can include **endolymphatic sac tumor, which is a papillary tumor of the petrous bone and can cause hearing loss; papillary cystadenomas of the epididymis; and the female counterpart, cystadenoma of the broad ligament (Zbar et al, 1996; Shehata et al, 2008).**

Because of the high incidence of RCC in patients with VHL disease, the urologist's primary role is careful surveillance so that small tumors can be identified and treated before they metastasize. Although central nervous system hemangioblastomas account for more than half of the deaths in these patients, metastatic RCC is also a major cause of mortality and in some accounts is the leading cause of death in this population (Maher et al, 1990; Reichard et al, 1998). Accordingly, annual or perhaps biannual CT examinations are advised.

Classification

Patients with VHL are subdivided into groups based on disease presentation, and each group has a specific *VHL* gene aberration. VHL type 1 is the most common form of the disease and is characterized by a tendency to develop tumors in the eyes, brain, spinal cord, kidney, and pancreas. VHL type 2 is less common. VHL type 2 differs from type 1 in that affected family members are at high risk to develop pheochromocytomas. VHL type 2 is further divided into types 2A, 2B, and 2C. Individuals in families with VHL type 2A develop pheochromocytomas but have a low risk for RCC (this type of VHL is uncommon). Those with VHL type 2B develop pheochromocytomas and have a high risk for RCC. Patients with type 2C VHL have familial pheochromocytoma without hemangioblastomas and clear cell RCCs (Zbar et al, 1996; Shehata et al, 2008) (Table 131-3).

Histopathology

When present, renal cysts and tumors often are multiple and bilateral. The cysts usually simulate simple benign cysts, with flattened epithelium that some investigators consider precancerous. In VHL patients, cysts larger than 2 cm are more likely than smaller cysts to have components of RCC (Poston et al, 1993). Frank cancer usually appears between the ages of 20 and 50 years (Jennings and Gaines, 1988). Others found that the hyperplastic

cells lining cysts frequently resembled the clear cell type of RCC, the most common type in these patients (Loughlin and Gittes, 1986). Ibrahim and colleagues (1989) studied the cysts adjacent to carcinomas and found, much as in tuberous sclerosis, that the karyotype resembled that of the tumors. This similarity is evidence that the hyperplastic cells of the cyst lining are precursors of the carcinomas.

Solomon and Schwartz (1988) believed that a spectrum of pathology is found within the kidneys of patients with VHL disease. At one extreme is a simple cyst with a single layer of bland epithelium. The next step is a typical proliferative cyst with layers of epithelial cells. In the ensuing step, there are complex neoplastic projections into the cyst lumen. If one agrees with the arbitrary distinction between adenoma and carcinoma on the basis of size, the next stage would be adenoma. Finally, there is full-blown RCC. All of these stages may be found within a single kidney (Solomon and Schwartz, 1988).

Evaluation

In patients with a known family history of VHL, the diagnosis can be made based on the presence of a single retinal or cerebellar hemangioblastoma, RCC, or pheochromocytoma (Melmon and Rosen, 1964; Couch et al, 2000). In such families, germline mutations may be present without clinical manifestations, and the patient should be screened for this mutation. For patients who do not have a family history, the diagnosis requires two or more cardinal manifestations, such as retinal or cerebellar hemangioblastomas, or a single hemangioblastoma and an additional characteristic lesion.

Ultrasonography is useful in diagnosing the typical benign renal cystic features of VHL disease: absence of internal echoes, well-defined margins, and acoustic enhancement. On CT, sharp thin walls are seen around homogeneous contents without enhancement after contrast medium injection. Because multiple lesions (cysts, tumors, or both) are often present, CT frequently is more useful than ultrasonography. CT often is useful in examining the adrenal glands for pheochromocytomas.

TABLE 131-3 Classification of von Hippel-Lindau Disease

TYPE	CLINICAL CHARACTERISTICS
1	Without pheochromocytoma
2	With pheochromocytoma
2A	Without renal cell carcinoma or pancreatic cysts
2B	With renal cell carcinoma and pancreatic cysts
2C	Familial pheochromocytoma without hemangioblastomas and clear cell renal cell carcinoma

When the lesions are small, it is impossible to distinguish tumors from cysts. In such cases, patients should have regular CT scans with narrow-screen collimation (Levine et al, 1982). With larger lesions, and whenever RCC is suspected, renal angiography with magnification or subtraction is advisable. This type of study helps to reveal any additional tumors and indicates the appropriateness of conservative surgery (Kadir et al, 1981; Loughlin and Gittes, 1986). Intra-arterial administration of epinephrine is sometimes helpful, because it causes vasoconstriction of the normal vessels but has no effect on tumor neovascularity.

MRI has not been very useful for small tumors of the kidney, unless the shape of the kidney is altered. The lesions on MRI have a signal intensity that is similar to that of normal renal parenchyma on T1- and T2-weighted images. However, gadolinium is useful because it enhances RCC. The heterogeneous nature of the larger tumors makes them more readily diagnosed (Rominger et al, 1992).

Screening

The genetic nature of VHL disease mandates careful screening. However, because of molecular genetic advances, the screening process for the disease in family members can now be more selective. Previously, asymptomatic relatives required routine ophthalmoscopic examination to rule out retinal angiomas, as well as frequent abdominal CT scans. Now only genetically affected family members require screening (Table 131-4).

Treatment

The treatment of patients with VHL requires a multidisciplinary approach, because the involvement of multiple organ systems and numerous medical problems is inherent to this disease. Because the tumors that characterize VHL disease are frequently multiple, bilateral, and recurrent, the goals of treatment for patients who have VHL disease are not as straightforward as the goals of treatment for patients who have sporadic tumors. Close surveillance and minimization of surgical procedures constitute the mainstay of treatment. For patients who have VHL disease, and all patients who have hereditary cancer syndromes, the goal of treatment is cancer control, not cancer cure, and preservation of functional parenchyma to avoid the morbidity associated with renal or adrenal loss. In patients who have VHL disease, surgical resection is performed with the understanding that microscopic disease probably is left behind. At present, open nephron-sparing surgery should be considered the standard of care for treating low-grade RCC in the setting of VHL disease. Patients with high-grade disease are still probably best served with bilateral nephrectomy. With the objective of sparing as much renal parenchyma as possible and preventing metastasis of the lesions already present, it is not curative surgery (Reed and Parekh, 2009). Although this approach does not reduce the risk of recurrence, reported to be 75% to 85%, the 10-year disease-specific survival rates are quite high (81% to 94%) (Malek

TABLE 131-4 Screening Protocol for Patients and Families with von Hippel-Lindau Disease

STUDY	AFFECTED PERSONS	RELATIVES AT RISK
Physical examination	Annual	Annual
24-Hour urine collection for metanephrines and normetanephrines	Annual	Annual
Funduscopy	Annual	Annual (age 10-60 yr)
Gadolinium MRI brain scan (or CT)	Every 3 yr from age 10-50 yr; every 5 yr thereafter	Every 3 yr from age 15-40 yr then every 5 yr until age 60 yr
Abdominal evaluation	Annual RUS with abdominal CT scan every 3 yr (more frequently if multiple renal cysts present)	Annual RUS with abdominal CT scan every 3 yr from age 20-65

CT, computed tomography; MRI, magnetic resonance image; RUS, renal ultrasonography.

et al, 1987; Steinbach et al, 1995; Roupert et al, 2003; Ploussard et al, 2007). Classically, the survival rate after nephrectomy has been only 50%. Because most of these tumors are low grade, a nephron-sparing approach provides very good survival rates while avoiding the diminished quality of life that comes with bilateral nephrectomy and subsequent dialysis and transplantation. Laparoscopic and percutaneous image-guided ablative techniques, such as radiofrequency ablation and cryoablation, have also been used and are currently under investigation.

Given the high risk of multiple and bilateral pheochromocytomas in patients who have VHL disease, bilateral adrenalectomy can lead to the loss of all adrenal function. Preservation of normal adrenocortical function should be a primary surgical goal, because medical replacement therapy is associated with decreased quality of life (Telenius-Berg et al, 1989). Partial adrenalectomy can preserve normal adrenal function and avoid this morbidity. Identification of small pheochromocytomas may enable laparoscopic preservation of adrenal function and maintain quality of life in these complicated patients. The small size and lack of function of these tumors make them ideal for partial adrenalectomy; however, recurrences may develop in 15% of patients (Walther et al, 1999a, 1999b).

Papillary cystadenomas of the epididymis can be unilateral or bilateral and occur in approximately 10% to 26% of men who have VHL disease (Horton et al, 1976; Lamiell et al, 1989). They seem to have no malignant potential. Surgery is not performed for these lesions unless the patient experiences severe pain.

KEY POINTS: MULTIPLE MALFORMATION SYNDROMES

- Tuberous sclerosis complex is an autosomal dominant condition that includes the triad of epilepsy, mental retardation, and adenoma sebaceum. It is associated with renal cysts (20% of patients), renal AML (40% to 80%), and RCC (2%).
- There are two different gene mutations associated with tuberous sclerosis: *TSC1* on chromosome 9 and *TSC2* on chromosome 16.
- VHL disease is an autosomal dominant syndrome associated with cerebellar and retinal hemangioblastomas; cysts of the pancreas, kidney (76%), and epididymis; pheochromocytoma (10% to 12%); and clear cell RCC (50% incidence, and 30% to 40% incidence of death).
- VHL disease is associated with an inherited mutation of the *VHL* gene on chromosome 3.
- *VHL* is a tumor suppressor gene involved in regulation of HIF target genes, including *VEGF*; abnormal or absent *VHL* leads to increased tissue levels of specific growth factors and, in particular, *VEGF*, the most prominent growth factor in RCC.

MULTICYSTIC DYSPLASTIC KIDNEY

MCDK is a developmental anomaly resulting in multiple cysts of varying sizes, without identifiable normal renal parenchyma. These kidneys have no function by definition, and usually the contralateral kidney is normal and exhibits compensatory hypertrophy. Only unilateral involvement is compatible with life. The kidney often does not have a reniform appearance, and it is typically associated with an atretic ureter with no connection between glomerulus and calyces. Typically, the kidney has the appearance of a bunch of grapes, with little stroma between the cysts (Fig. 131-17). Renal size is highly variable, ranging from a small nubbin of tissue to a very large mass that fills most of the abdomen. In fact, MCDK is the second most common cause of an abdominal mass in a newborn, after hydronephrosis.

MCDK can be of two types: the infundibulopelvic type, with the atresia involving both the renal pelvis and the ureter, and the less common hydronephrotic type, in which only the upper ureter is atretic (Felson and Cussen, 1975). In both cases, the ureters are

Figure 131-17. A typical multicystic dysplastic kidney having the appearance of a bunch of grapes. The kidney is composed almost entirely of cysts with very little stroma.

absent or atretic and the renal vessels are hypoplastic. MCDK can also rarely be secondary to ureterocele that have caused complete obstruction. It can rarely be seen in one half of a duplex kidney (usually the upper pole associated with an ectopic ureter) or in other abnormalities such as a horseshoe kidney.

Etiology

Many theories have been offered to explain the cause of MCDK. Clearly, it is a result of an error in renal development. Some have proposed that the multicystic kidney is an extreme form of obstructive hydronephrosis that occurs secondary to atresia of the ureter or renal pelvis. The fact that the left kidney is the one more often affected supports this view, because this is the kidney more often associated with primary obstructive megaureter (Glassberg, 1977) and UPJO (Johnston et al, 1977). Several investigators have attempted to establish an animal model of MCDK by ligating the ureter at various points in gestation (Beck, 1971; Tanagho, 1972; Fetterman et al, 1974). This approach is not effective in middle or late gestation; early ligation of the fetal lamb ureter produces renal dysplasia but not multicystic dysplasia (Beck, 1971). Similarly, other investigators have been able to induce dysplasia, but no one as yet has been able to induce an MCDK.

Another theory stems from the “ureteric bud theory” as proposed by Mackie and Stephens (1975). This theory hypothesizes that MCDK may result from abnormal interaction between the ureteric bud and metanephric mesenchyme. Mutations in genes such as *EYA1*, *SIX1*, *WNT*, *WT-1*, *GNF*, *AT2*, and *PAX2* are known to have important roles in ureteric bud development and have been identified in multiple human syndromes with renal dysplasia (Pope et al, 1999). These studies linking genetic mutations with renal dysplasia support the ureteric bud theory in the pathogenesis of MCDK and may also explain its frequent association with other urinary tract anomalies (Hains et al, 2009). In addition, Hildebrandt (1894) suggested that failure of the union between the ureteric bud and the metanephric blastema leads to cystic dilation in the latter; this hypothesis, like the obstructive view, is supported by the high incidence of concomitant ureteral atresia.

Although the ureteric bud theory and the obstruction theory may at some level go hand in hand, there is no question that there are several gene-mediated processes that go awry in the process of making a developmentally abnormal MCDK. These genes and their proteins are currently potential targets for both therapeutic intervention and research to further elucidate the mechanisms that cause MCDK.

Clinical Features

Multicystic dysplasia is the most common type of renal cystic disease and is the second most common cause of an abdominal mass in infants (Longino and Martin, 1958; Melicow and Uson, 1959; Griscom et al, 1975). Most cases in the current era are diagnosed by prenatal ultrasonography, and the incidence is 1 per 1000 to 4000 live births (Kalyoussef et al, 2006). There is a male preponderance (55% to 70%), and studies conflict as to whether MCDK is more common on the right or left side.

The contralateral system frequently is abnormal. For example, contralateral UPJO is found in 3% to 12% of infants with MCDK, and contralateral vesicoureteral reflux is seen in 18% to 43% of infants (Heikkinen et al, 1980; Atiyeh et al, 1992; Flack and Bellinger, 1993; Wacksman and Phipps, 1993; Al-Khaldi et al, 1994).

The natural history of MCDK is benign; the incidence of complications is extremely rare; and approximately 40% of MCDKs will spontaneously involute. Although anecdotal case reports exist, available large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm (Wacksman and Phipps, 1993; Tilemis et al, 2003; Truong et al, 2003; Rabelo et al, 2004; Farnham et al, 2005; Narchi, 2005a, 2005b; Onal and Kogan, 2006). Although hypertension is a rare but recognized sequela of MCDK, it is reasonable to follow patients with MCDK conservatively. The primary care provider should monitor patients with MCDK for hypertension, abdominal mass, and urinary tract infection.

Histopathology

Multicystic kidneys with large cysts tend to be large with little stroma, whereas those with small cysts typically are smaller and more solid. Likewise, the blood supply is variable, ranging from a pedicle with small vessels to no pedicle at all (Parkkulainen et al, 1959). Usually the ureter is partly or totally atretic, and the renal pelvis may be absent. Griscom and colleagues (1975) referred to the form without a renal pelvis as *pyeloinfundibular atresia* and reported finding no evidence of communication between the cysts. However, others have shown distribution of contrast medium among the cysts by means of connecting tubules (Saxton et al, 1981). Microscopically, the cysts are lined by low cuboidal epithelium, are surrounded by collars of spindle cells, and are filled with proteinaceous or sanguineous fluid. They are separated by thin septa of fibrous tissue and primitive dysplastic elements, especially primitive ducts. Immature-appearing cartilage is often present in the tissue. Frequently, immature glomeruli are present, and on occasion a few mature glomeruli are seen (Fig. 131-18).

Evaluation

MDCK is most often identified by prenatal ultrasonography, and in newborns ultrasonography is usually repeated (once within the first few days of life and again 1 month later) to confirm the diagnosis and to evaluate the contralateral kidney and bladder. In a few cases, it is difficult to differentiate multicystic kidney disease from severe hydronephrosis (Gates, 1980; Hadlock et al, 1981). In general, the multicystic kidney has a haphazard distribution of cysts of various sizes without a larger central or medial cyst and without visible communications among the cysts. Frequently, very small cysts appear among the large cysts. By comparison, in UPJO, the cysts or calyces are organized around the periphery of the kidney; connections usually can be demonstrated between the peripheral cysts and a central or medial cyst that represents the renal pelvis; and there is an absence of small cysts among the larger cysts (Fig. 131-19).

Figure 131-18. Disorganized development of kidney consistent with multicystic dysplastic kidney showing primitive glomeruli, tubules, and mesenchyme. (From Ordonez NG, Rosai J. Urinary tract. In: Rosai J, editor. Rosai and Ackerman's surgical pathology. 9th ed. Edinburgh: Mosby; 2004.)

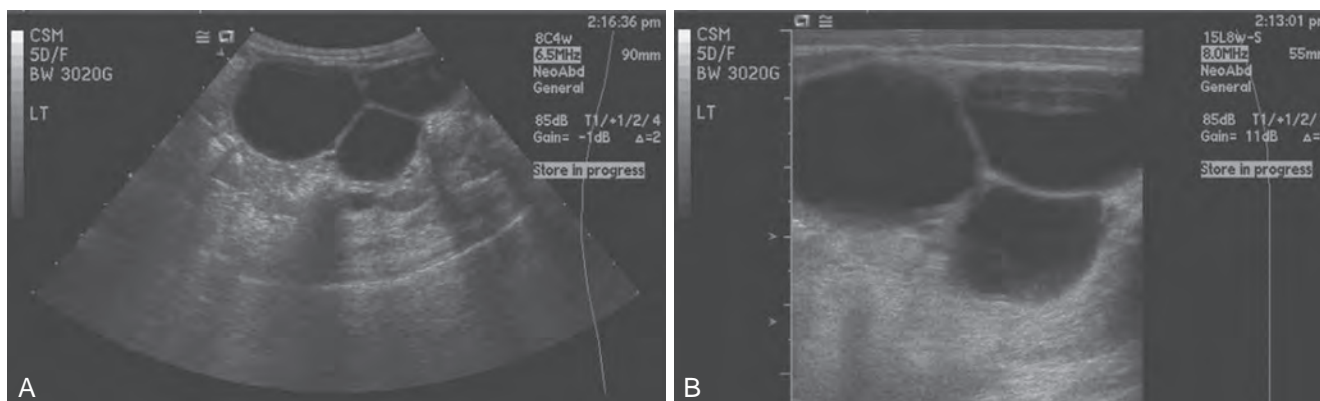

Figure 131-19. A and B, Renal ultrasonogram of large left multicystic dysplastic kidney. There are multiple large cysts. No definite renal cortex is seen.

In these difficult cases, radioisotope studies may be helpful. Hydronephrotic kidneys usually show some function on a dimercaptosuccinic acid (DMSA) or technetium-99m mercaptoacetyl-triglycine (^{99m}Tc -MAG3) scan, whereas renal uptake is seldom seen in multicystic kidneys (Fig. 131-20). Angiography reveals an absent or small renal artery in the multicystic kidney, but this study is rarely indicated. Cystoscopy may reveal a hemitrigone and absent ureteric orifice on the affected MCDK side; however, more often an orifice is present, but retrograde urography demonstrates ureteral atresia. Again, this study is seldom performed. As mentioned previously, a voiding cystourethrogram (VCUG) is usually indicated in the workup, because of the high incidence of reflux into the contralateral single functioning kidney. Some authors, however, have started to advocate that the VCUG is of little value if serial high-quality ultrasound findings are consistent with MCDK and

demonstrate a normal bladder and contralateral kidney. A VCUG is not necessary unless clinically indicated later in life (Ismaili et al, 2005; Welch and Wacksman, 2005; Onal and Kogan, 2006).

Treatment and Prognosis

It has often been stated that the multicystic kidney can be ignored unless its bulk is inconvenient (Pathak and Williams, 1964; Griscom et al, 1975), and attention should be directed instead to identifying any abnormalities of the contralateral urinary tract. Large MCDKs are known to interfere with respiratory and digestive function simply because of their mass effect. Intervention for these large masses may need to be undertaken to relieve these problems. Nephrectomy for MCDK may also be necessary to correct the rare cases of associated hypertension or if a cyst

Figure 131-20. Technetium-99m mercaptoacetyl-triglyceride renogram revealing a normally functioning right kidney and no function on the left, which is consistent with a left multicystic dysplastic kidney.

has ruptured spontaneously or secondary to trauma (to relieve pain or hemorrhage).

A nonfunctioning hydronephrotic kidney could be mistaken for a multicystic kidney, although complete nonfunction on a nuclear medicine study is unusual in kidneys affected by UPJO. Fortunately, if the correct diagnosis is missed in such a case, there are unlikely to be significant consequences, because a totally nonfunctioning hydronephrotic kidney is rarely salvageable and probably will cause no problems other than a predisposition to infection or hypertension.

The probability of malignant transformation is estimated to be extremely low and believed by many to be nonexistent (Avni et al, 1987; Gordon et al, 1988; Wacksman and Phipps, 1993; Narchi, 2005b). Fewer than 15 cases of malignant degeneration have been reported in MCDK. Roughly half have been identified as RCC and half as Wilms tumor, and there has been one reported mesothelioma. Recommendations for addressing this risk range from early nephrectomy of the MCDK to minimal follow-up with no imaging and only periodic abdominal examination by the primary care physician (PCP). Many pediatric urologists will perform ultrasound surveillance every 3 to 12 months, but there has been no conclusive evidence that this is beneficial or cost-effective (Perez et al, 1998; Onal and Kogan, 2006).

There has also been much debate in contemporary series regarding hypertension in MCDK. The various case reports and small series that have been reviewed offer conflicting data on the issue. An additional confounding factor is that MCDK is often associated with contralateral abnormalities, such as UPJO and reflux. Thus groups have had difficulty determining if hypertension is associated with contralateral abnormalities or with MCDK. Several small series have reported patients with MCDK and hypertension who were cured with nephrectomy (Javadpour et al, 1970; Suskind et al, 1989; Angermeier et al, 1992; Webb et al, 1997; Snodgrass, 2000). Although these reports demonstrate that hypertension can occur with MCDK, most large series support the rarity of hypertension in association with MCDK. Several studies, including the report from the Multicystic Kidney Registry in 1993, have demonstrated the incidence of hypertension in patients with MCDK and long-term follow-up to be less than 1% (Wacksman and Phipps, 1993; Gough et al, 1995; Perez et al, 1998; Farnham et al, 2005). One study, however, demonstrated a much higher incidence of hypertension than the other MCDK series (Seeman et al, 2001). This could be a result of the more stringent measurement of BP applied, although

these patients were examined at a much later age than in other series, which may also have contributed to the higher detected incidence of hypertension. Two of those four patients with hypertension had concomitant abnormalities; thus it was concluded that increased BP is mainly associated with contralateral kidney damage regardless of the presence or absence of the dysplastic kidney (Seeman et al, 2001). In summary, hypertension is a rare but recognized sequela of MCDK. However, there is a suggestion that with more diligent monitoring, its incidence would increase. Therefore it is reasonable to follow patients with MCDK conservatively, realizing that hypertension can exist and should be assessed periodically. Because hypertension can be discovered on an examination by the PCP, the potential for this problem does not require urologic follow-up, only an informed PCP and family (Farnham et al, 2005).

KEY POINTS: MULTICYSTIC DYSPLASTIC KIDNEY

- MCDK is a developmental anomaly resulting in multiple cysts of varying sizes, is without identifiable normal renal parenchyma, is associated with active expression of genes involved with nephrogenesis, and has a changing morphology.
- Kidneys usually get smaller or disappear from view on imaging studies (i.e., renal aplasia), very occasionally increase in size, and very rarely are associated with Wilms tumor.
- There is no clear indication for removal of the kidney, unless an increased amount of solid tissue is identified.
- Large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm.
- Fifteen percent of patients have associated contralateral reflux, and debate exists regarding whether or not to obtain a VCUG in all or only in those with some degree of fullness in the contralateral collecting system.

BENIGN MULTILOCLAR CYST (CYSTIC NEPHROMA)

Benign multilocular cyst (multilocular cystic nephroma) is a multilocular cystic neoplastic lesion in the kidney that falls in a spectrum of diseases along with multilocular cyst with partially differentiated Wilms tumor, a multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor (Fig. 131-21). These four

Figure 131-21. The spectrum of multilocular cystic lesions in children and adults. There is no evidence that one lesion can convert into the other. Benign cystic partially differentiated Wilms tumor and multilocular cystic renal cell carcinoma act as benign lesions. When nodules of tumor are present, the lesion should be considered malignant, although the prognosis of this lesion, as well as cystic Wilms tumor and cystic renal cell carcinoma, seems to be better than that of the corresponding solid lesions. It is not clear whether clinical examples of “multilocular cyst with nodules of renal cell carcinoma” actually exist, but this entity is placed in the spectrum for consideration. For simplicity, the multilocular-appearing lesions of other cystic tumors (e.g., cystic oncocyoma, cystic hamartoma of the renal pelvis) are not included in the figure.

lesions form a spectrum, with benign multilocular cyst at the most benign extreme and cystic Wilms tumor at the most malignant extreme. There has been some debate as to whether these lesions represent a spectrum of one disease with a common cause.

A multilocular cyst is not a renal segment affected by multicystic kidney disease; these conditions differ clinically, histologically, and radiographically. However, controversy continues about whether the multilocular cyst is a segmental form of renal dysplasia (Powell et al, 1951, Osathanondh and Potter, 1964; Johnson et al, 1973), a hamartomatous malformation (Arey, 1959), or a neoplastic disease (Boggs and Kimmelsteil, 1956; Christ, 1968; Fowler, 1971; Gallo and Penchansky, 1977). The confusion arises in part from the variability of the histologic picture: the appearance of the primitive stroma; the maturity of tubular and even on occasion of muscle elements; and the degree of epithelial atypia that differs not only from patient to patient but also within the same lesion.

Clinical Features

The great majority of cases (95%) manifest before the age of 4 years or after 30 years. If younger than 4 years, the patient is twice as likely to be male; if older than 30 years, the patient is eight times as likely to be female (Eble and Bonsib, 1998).

The signs and symptoms differ according to the age at presentation. In children, an asymptomatic flank mass is the most common finding, whereas most adults have a flank mass, abdominal pain, or hematuria. The bleeding is felt to be secondary to herniation of the cyst through the transitional epithelium into the renal pelvis (Uson and Melicow, 1963; Aterman et al, 1973; Madewell et al, 1983).

Seven cases of bilateral benign multilocular cysts of the kidney have been described (Castillo et al, 1991), and recurrence after excision has been rarely described (Geller et al, 1979). There are also at least two instances in which multilocular cysts arose in kidneys known to have been normal previously (Uson and Melicow, 1963; Chatten and Bishop, 1977). Such cases support a neoplastic theory of the origin of this lesion.

Histopathology

These lesions are bulky and are circumscribed by a thick capsule. Normal renal parenchyma adjacent to the lesion frequently is compressed by it. The lesion may extend beyond the renal capsule into the perinephric space or renal pelvis. The loculi, which range from a few millimeters to centimeters in diameter, do not communicate. They contain clear, straw-colored or yellow fluid and are lined by cuboidal or low columnar epithelial cells. In some cases, eosinophilic cuboidal cells project into the cyst lumen, creating a hobnail appearance (Madewell et al, 1983). The septa of a benign multilocular cyst are composed of fibrous tissue in which well-differentiated tubules may be present, but poorly differentiated tissues and blastemal cells are not present (Joshi and Beckwith, 1989).

In children, although there may be a continuum from benign multilocular cyst to cystic Wilms tumor, and although all of these lesions may be derived from similar cells or tissues, no evidence suggests that one entity transforms into another. Furthermore, none of the genetically determined conditions associated with Wilms tumor (e.g., hemihypertrophy, aniridia) has accompanied a benign multilocular cyst (Banner et al, 1981).

In adults, there also is a spectrum of multilocular cystic lesions. Multilocular cystic RCC in adults falls in the spectrum between a benign multilocular cyst and a cystic malignant tumor, such as a multilocular cystic RCC, a cystic RCC, a cystic oncocyoma, or a cystic hamartoma of the renal pelvis (Eble and Bonsib, 1998; Kirsh et al, 1999). The cystic component of the tumor at the carcinomatous end of the spectrum in both children and adults (i.e., cystic Wilms tumor and cystic RCC) improves the prognosis of the malignant lesion (Kirsh et al, 1999). In adults, as in children, there is no evidence that one lesion can convert into another (Fig. 131-22).

Evaluation

A number of tests may be useful, including ultrasonography, CT, MRI, cyst puncture with aspiration and double-contrast cystography, and arteriography. Ultrasonography and CT can distinguish multicystic kidneys from multilocular cysts, but neither study is sufficiently reliable to distinguish among multilocular cysts, multilocular cysts with foci of Wilms tumor or adenocarcinoma, mesoblastic nephromas, cystic Wilms tumors, and clear cell sarcomas. Typically, the septa are highly echogenic with sonolucent loculi, although if there is debris in a loculus, it may appear more solid. On CT the septa are less dense than normal parenchyma. Calcification is rarely visible in such lesions in children (Madewell et al, 1983).

Treatment

The treatment for any multilocular cystic lesion, even the most benign variant, is nephrectomy. If the lesion is localized enough and there is well-preserved normal tissue, excision of the lesion or partial nephrectomy is feasible. Children who have a multilocular cyst with nodules of Wilms tumor or a cystic Wilms tumor should be treated as for Wilms tumor, according to the National Wilms Tumor Study (NWTs) recommendations for the appropriate stage of disease, recognizing the generally favorable outlook. Similarly, cystic RCC in adults should be managed as a malignant lesion, again recognizing its better prognosis. In adults, benign multilocular cysts more often are associated with larger amounts of normal renal tissue, making partial nephrectomy more often feasible.

If enucleation or partial nephrectomy is chosen, recurrence is possible. However, with more Wilms tumors being treated by local excision, the case for enucleation or partial nephrectomy combined with close follow-up by ultrasonography and CT is stronger, even if malignancy is found within the lesion. By comparison, if a clear cell sarcoma is found after enucleation, the remaining ipsilateral renal tissue should be removed because of the aggressiveness of this cancer. The recurrence of a multilocular cyst not containing malignancy probably reflects inadequate excision of the initial lesion.

KEY POINTS: BENIGN MULTILOCULAR CYST

- A benign multilocular cyst is a benign, nondysplastic, neoplastic lesion that occurs most commonly either before the age of 4 years, most frequently in males, or after the age of 30 years, predominantly in females.
- The only way to determine the diagnosis of a multilocular cystic lesion identified on imaging studies, in either a child or an adult, is by surgical excision.
- Benign multilocular cyst is thought to fall at the benign end of a spectrum of the same disease process that also includes multilocular cyst with partially differentiated Wilms tumor, multilocular cyst with nodules of Wilms tumor, or cystic Wilms tumor at the most malignant end of the spectrum.

SIMPLE CYSTS

Simple cysts are the most common cystic lesions found in the human kidney. They are usually oval to round; may be solitary or multiple, unilateral or bilateral; and are filled with plasma-like clear or straw-colored fluid (Nahm and Ritz, 2000; Terada et al, 2002). They are not connected to any part of the nephron, although they may originate initially from a portion of the nephron.

Simple cysts may manifest at any time in utero and have been diagnosed as early as 14 weeks of gestation. Ultrasonography done on 29,984 fetuses in succession revealed 0.09% of 11,000 pregnancies to have renal cysts (Blazer et al, 1999). Between birth and 18 years of age, the incidence of simple renal cysts is fairly stable,

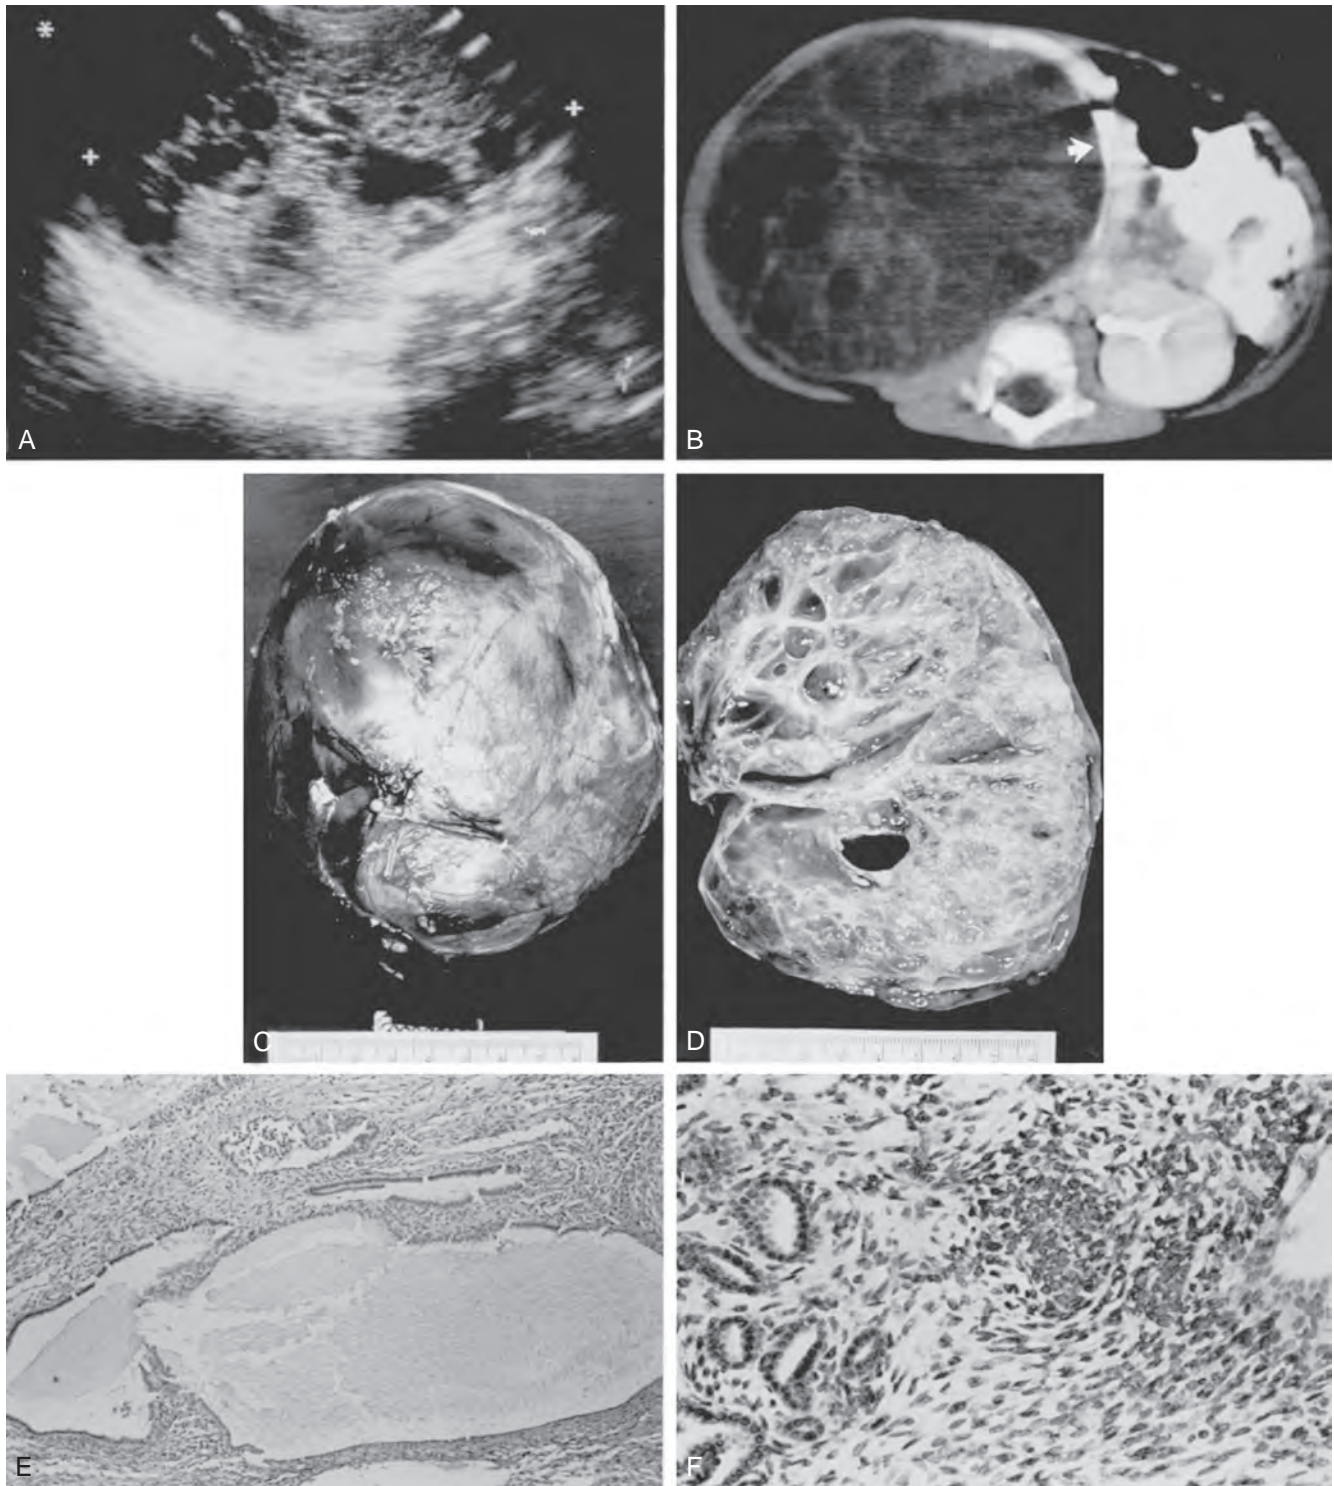

Figure 131-22. A 4-year-old girl with a right-sided abdominal mass. **A**, Renal ultrasonogram shows multiple cysts throughout the left kidney. **B**, On contrast medium-enhanced computed tomography scan, a large, smoothly outlined left renal mass is seen with fine septa throughout the mass. Residual preserved parenchyma and the pelvicalyceal system are compressed medially and pushed to the contralateral side (arrow). **C**, Uncut gross specimen reveals a smooth-walled, encapsulated renal mass. **D**, Cross section of mass reveals multiple noncommunicating loculations. **E**, On histology, a hypocellular cystic area is seen with monotonous stroma (100 \times). **F**, Between loculi, nests of blastemal cells are visualized along with tubular elements (left), making the diagnosis of multilocular cyst with partially differentiated Wilms tumor (200 \times).

ranging from 0.1% to 0.45%, with an average incidence of 0.22% (McHugh et al, 1991). However, in adults the frequency rises with age, with an incidence of 20% by age 40 years and as high as 50% after age 60 years (Kissane and Smith, 1975; Laucks and McLachlan, 1981). Most reports show no gender predilection; however, in at least two studies, men were affected more frequently than women (Bearth and Steg, 1977; Tada et al, 1983).

Clinical Features

In both children and adults, cysts rarely call attention to themselves. Instead, they are discovered incidentally on ultrasonography, CT, or urography. However, cysts can produce an abdominal mass or pain, hematuria secondary to rupture into the pelvicalyceal system, and hypertension secondary to segmental ischemia (Rockson et al, 1974; Lüscher et al, 1986; Papanicolaou et al, 1986). Cysts can cause calyceal or renal pelvic obstruction as well (Wahlqvist and Grumstedt, 1966; Evans and Coughlin, 1970; Hinman, 1978; Barloon and Vince, 1987). They may or may not increase in size with time.

Cysts can rupture into the pelvicalyceal system, maintain a communication, and become a pseudocalyceal diverticulum. The reverse is also possible: Closure of the communication of a diverticulum can create a simple cyst (Mosli et al, 1986; Papanicolaou et al, 1986). These two sequences of events can be distinguished only by histologic examination. Theoretically, diverticula should have linings of transitional epithelium, whereas simple cysts should be lined by a single layer of flattened or cuboidal epithelium.

Histopathology

Simple cysts vary considerably in size, ranging from less than 1 cm to greater than 10 cm. The majority are less than 2 cm in diameter, however (Tada et al, 1983). The wall is fibrous and of varying thickness and has no renal elements. The cyst lining is glistening and usually smooth and histologically is a single layer of flattened or cuboidal epithelium, and the cysts are filled with a clear, serous fluid. Because cysts are increasingly common with age, they have been considered an acquired lesion. Some cysts may be trabeculated by partial septa that divide the cavity into broadly interconnecting loculi. These septated simple cysts should not be confused with multilocular cysts. The cysts are often cortical and distort the renal contour, but they may be deep cortical or apparently medullary in origin. They do not communicate with the renal pelvis. The walls typically are thin and transparent but may become thickened, fibrotic, and even calcified, possibly from earlier hemorrhage or infection (Torres and Grantham, 2008).

Evaluation

Most simple cysts are identified incidentally. One can safely make the diagnosis of a classic benign simple cyst by ultrasonography when the following criteria are met: (1) absence of internal echoes, (2) presence of a sharply defined, thin, distinct wall with a smooth and distinct margin, (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst, and (4) a spheric or slightly ovoid shape (Goldman and Hartman, 1990). If all of these criteria are satisfied, the chance that malignancy is present is negligible (Fig. 131-23) (Lingard and Lawson, 1979; Livingston et al, 1981).

When some of these criteria are not met (e.g., when there are septations, irregular margins, calcifications, or suspect areas), further evaluation by CT, or perhaps needle aspiration or MRI, is indicated (Bosniak, 1986). A cluster of cysts is another indication for further study, because they may be hiding a small carcinoma. CT is better than ultrasonography in defining such a camouflaged lesion (Bosniak, 1986). Peripelvic cysts often require CT confirmation, because they frequently are interspersed among structures of the collecting system and hilum, which can create artificial echoes (Bosniak, 1986).

Figure 131-23. Ultrasonographic appearance of a 4-cm simple renal cyst. This meets the definition of a true simple cyst: (1) absence of internal echoes; (2) sharply defined, thin, distinct wall with a smooth and distinct margin; (3) good transmission of sound waves through the cyst with consequent acoustic enhancement behind the cyst; and (4) spheric or slightly ovoid shape.

The CT criteria for a simple cyst are similar to those used in ultrasonography: (1) a sharp, thin, distinct, smooth wall and margin, (2) a spheric or ovoid shape, and (3) homogeneous content. When these criteria are respected, the accuracy of diagnosis of a simple cyst by CT approaches 100% (Fig. 131-24) (McClellan et al, 1979). The density ranges from -10 to +20 HU, similar to the density of water, and no enhancement should occur after the intravenous injection of contrast medium.

When the cyst fluid is hyperdense (i.e., between 20 and 90 HU), the cyst still is likely to be a simple cyst if no enhancement occurs when intravenous contrast agent is injected and if the other criteria of CT and ultrasonography are met. Hyperdense cysts must be evaluated with narrow window settings to make sure that they are homogeneous. Other criteria that must be met to avoid further evaluation of hyperdense cysts (e.g., cyst puncture or exploration) include size (the lesion should be 3 cm or smaller) and location (at least one fourth of the cyst's circumference should extend beyond the renal contour so that the smoothness of a good portion of the cyst can be evaluated) (Bosniak, 1991; Hartman et al, 1992). Because cysts have no blood vessels and do not communicate directly with nephrons, they should not enhance; enhancement therefore implies vascular tissue or contrast medium mixing with fluid. Enhancement of any nodular areas on the wall of the cyst or of a thickened septum within the cyst is taken as proof of vascularity within the lesion, and thus there should be a high index of suspicion for neoplasm.

When ultrasonographic or CT criteria are not met, conditions other than a simple cyst must be considered, such as complicated cysts (i.e., those containing blood, pus, or calcification) and cystic neoplasms. Cyst puncture and aspiration with or without contrast medium injection has been popular in the past, but with current imaging modalities the need for cyst puncture is very rare. The remaining indications for cyst puncture are (1) suspected infection, in which case puncture may be therapeutic as well as diagnostic, (2) the presence of low-level echoes on ultrasonography but a classic cyst on CT, and (3) a borderline lesion in a poor surgical candidate.

Two percent of simple cysts and 10% of RCCs contain calcium deposits, but calcification in simple cysts appears to be peripheral, whereas in tumors it is more central. When the cysts are numerous and bilateral, differentiation from ADPKD may be difficult if liver cysts are not also found. Because of the obvious implications, it is important to avoid a diagnosis of ADPKD in questionable cases

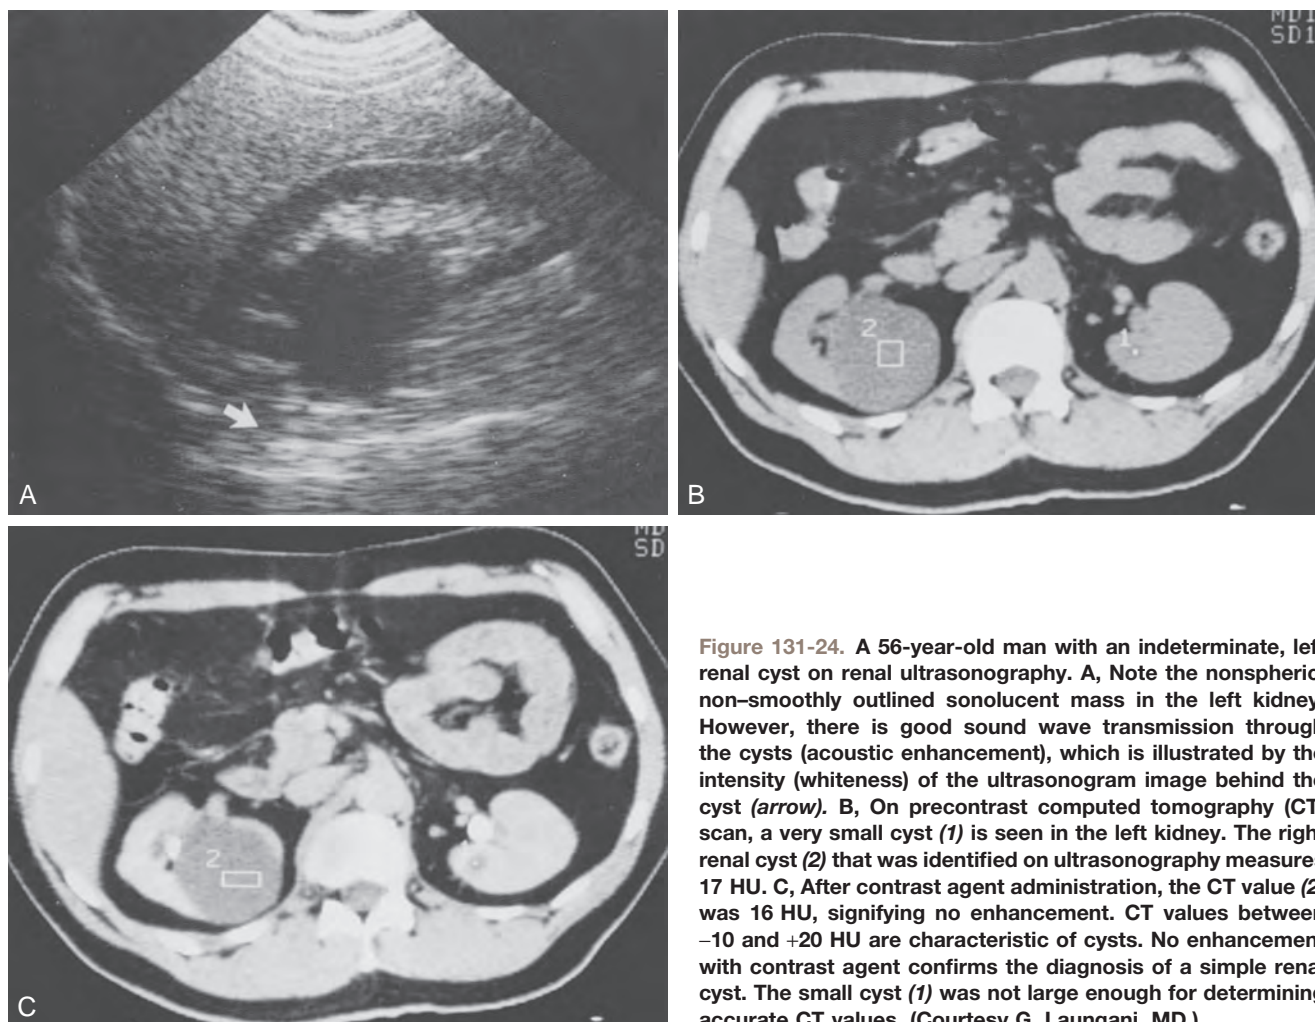

Figure 131-24. A 56-year-old man with an indeterminate, left renal cyst on renal ultrasonography. **A**, Note the nonspherical, non-smoothly outlined sonolucent mass in the left kidney. However, there is good sound wave transmission through the cysts (acoustic enhancement), which is illustrated by the intensity (whiteness) of the ultrasonogram image behind the cyst (arrow). **B**, On precontrast computed tomography (CT) scan, a very small cyst (1) is seen in the left kidney. The right renal cyst (2) that was identified on ultrasonography measures 17 HU. **C**, After contrast agent administration, the CT value (2) was 16 HU, signifying no enhancement. CT values between -10 and $+20$ HU are characteristic of cysts. No enhancement with contrast agent confirms the diagnosis of a simple renal cyst. The small cyst (1) was not large enough for determining accurate CT values. (Courtesy G. Laungani, MD.)

unless a familial history consistent with autosomal dominant transmission can be documented or the diagnosis confirmed by genetic testing.

MRI offers little information beyond that available from ultrasonography and CT, although it is more specific in identifying the nature of the cyst fluid. Marotti and colleagues (1987) found that if the fluid has low signal intensity (similar to that of urine) on T1-weighted images, the cyst is benign even if the wall is thick or septa are present. If this report is substantiated by additional studies, MRI may prove valuable in deciding which indeterminate cysts are benign and which should be considered for exploration. The T2-weighted images identify bloody fluid with an extremely bright image.

Classification

In an attempt to better categorize surgical and nonsurgical cysts in the kidney, Bosniak suggested a classification in 1986 that was clarified further in 1997 and modified by Israel and Bosniak in 2003 (Box 131-2). In addition, Wallis and colleagues (2008) suggested a modified Bosniak classification that can be used as a guideline to direct the need for surgical intervention in the pediatric population. They propose that in the absence of change or symptoms Bosniak class II cysts may be safely followed with periodic ultrasound imaging. Patients with Bosniak class III and class IV cysts have a significant chance of harboring malignancy, and surgical resection should be considered (Wallis et al, 2008).

Category I cysts are the typical benign cysts. Category II cysts are benign cystic lesions that are minimally complicated, such as by septations, small calcifications, infection, or high density, and do not require surgery. For example, when all the criteria for

BOX 131-2 Bosniak's Classification of Simple and Complex Cysts

CATEGORY I

Simple benign cyst with (1) good through-transmission (i.e., acoustic enhancement), (2) no echoes within the cyst, (3) sharply margined smooth wall; requires no surgery.

CATEGORY II

Looks benign with some radiologic concerns, including septation, minimal calcification, and high density; requires no surgery.

CATEGORY II F

Although calcification in wall of cyst may even be thicker and more nodular than in category II, the septa have minimal enhancement, especially those with calcium; requires no surgery.

CATEGORY III

More complicated lesion that cannot confidently be distinguished from malignancy, having more calcification, more prominent septation of a thicker wall than a category II lesion; more likely to be benign than malignant; requires surgical exploration and/or removal.

CATEGORY IV

Clearly a malignant lesion with large cystic components, irregular margins; solid vascular elements; requires surgical removal.

a simple cyst are met, except that a fine line of calcification or a short segment of slightly thickened calcification is seen in the wall or septa, the lesion should be considered a benign cyst, and exploration is not required. Another example is the cyst with fine traversing strands, perhaps containing calcium. In this case, exploration is not required unless the septa are numerous, irregular, or thick.

Category II F cysts (Israel and Bosniak, 2003) are complex cysts that cannot be classified as either category II or III. These lesions may contain increased calcification. The calcification may even be thicker and nodular, but although the septa may have minimal enhancement those septa with calcium do not enhance. Calcification seems to represent a less significant finding in making a lesion suspicious as a malignancy than previously thought. More focus is placed on tissue enhancement. There is little concern if calcification increases with time but much concern if the wall or septa becomes thicker or irregular. **Category II F cysts do not require surgical exploration** (Israel and Bosniak, 2003) (Fig. 131-25).

Category III cysts are more complicated lesions with radiologic features that are also seen in malignancy. One example is the lesion with more extensive calcification, especially if the wall is not pencil-point thin or is irregular. Other category III cysts are those with septations, suggesting a multilocular cystic lesion, or chronic infection with a thickened wall. These lesions are more problematic and require a surgical approach that is individualized. In some cases, one might consider violating the Gerota fascia to expose the kidney for examination of the lesion or partial nephrectomy.

Bosniak category IV lesions are cystic malignant tumors and are dealt with as such, namely, by radical nephrectomy.

Treatment and Prognosis

Once malignancy has been ruled out, surgical intervention for an asymptomatic cyst is not indicated (Gordon et al, 1979; Bartholomew et al, 1980; Ravden et al, 1980; Siegel and McAlister, 1980). Large renal cysts may cause abdominal or flank pain, although this pain may be caused by a coexisting problem (e.g., nephrolithiasis), and other sources of pain should be ruled out. Other symptoms that may arise as a result of simple cysts are pain resulting from hemorrhage into the cyst or calyceal or infundibular obstruction caused by cyst impingement. In rare cases, hypertension may occur, presumably from cyst compression causing segmental renal ischemia of the surrounding renal parenchyma. Cyst infection is a rare but potentially severe complication, with patients demonstrating fever, flank pain, and often a sympathetic pleural effusion (Torres and Grantham, 2008). Most of these patients are women, the most common pathogen is *Escherichia coli*, and urine cultures can often be negative.

Treatment of the simple cyst must thus be directed to the symptomatology. When a benign simple cyst causes pyelocalyceal obstruction or hypertension, the problem may be corrected either surgically, by unroofing the cyst, or percutaneously, by aspirating the fluid and perhaps injecting a sclerosing agent, particularly if fluid has reaccumulated after an earlier aspiration. Several sclerosing agents have been used, including glucose, phenol, iophendylate (Pantopaque), bismuth phosphate, and absolute ethanol, but none has been sufficiently impressive for its use to become dominant (Holmberg and Hietala, 1989). Infected cysts must be drained and appropriate antibiotics given. Percutaneous resection, intrarenal marsupialization (Hubner et al, 1990; Hulbert and Hunter, 1990; Meyer and Jonas, 1990), and laparoscopic unroofing (either transperitoneally or retroperitoneally) are all reasonable options for the treatment of symptomatic simple cysts.

Unilateral renal cystic disease is characterized by cysts of varying size appearing side by side, often more numerous at one pole. Except for its unilateral location, lack of extrarenal cyst formation, and the fact that these patients show no genetic background or progressive deterioration in renal function, the gross and histologic findings are indistinguishable from those of asymmetrical ADPKD (Lee et al, 1978; Kossow and Meek, 1982). It is important not to overdiagnose unilateral simple cyst disease, because the entity itself is rare, and when first identified in an individual it is more likely to represent a unilateral asymmetrical presentation of ADPKD. Because the entity seems to represent nothing more than multiple simple cysts lying side by side within a kidney, it seems reasonable to consider it as a variation of the presentation of simple cysts. Now that genetic studies are becoming available for ADPKD, tuberous sclerosis, and VHL disease, the diagnosis of unilateral renal cystic disease can more readily be confirmed (Fig. 131-26).

KEY POINTS: SIMPLE CYSTS

- Simple cysts are seldom seen in children; in adults, simple cysts are seen increasingly more frequently with age.
- For diagnosis of a benign simple cyst on ultrasonography, it should (1) have no internal echoes, (2) have a sharply defined, thin, distinct smooth wall, (3) be spheric or oval with no internal echoes, and (4) have good transmission of sound waves with acoustic enhancement behind the cyst. When these criteria are not met, CT with contrast enhancement must be performed.
- Relevant guidelines for determining when to explore or remove a complex cyst are often based on the Bosniak CT classification (see Box 131-2).

MEDULLARY SPONGE KIDNEY

The condition known as *medullary sponge kidney* (MSK; also known as *precalleal canalicular ectasia*) was recognized by Beitzke in 1908, and its radiographic features were described by Lenarduzzi in 1939.

Figure 131-26. Unilateral renal cystic disease. Diffuse simple cysts were evident in one kidney. There was no discrete mass or evidence of multiple malformation syndrome. (Courtesy Jeffrey Newhouse, MD.)

Figure 131-27. Contrast-enhanced maximum intensity projection three-dimensional image from multidetector-row computed tomography (CT) urogram shows characteristic papillary blush (arrows) associated with scattered calculi within the dilated collecting tubules. The CT demonstration is equivalent to the well-documented intravenous pyelography findings. (From Maw AM, Megibow AJ, Grasso M, et al. Diagnosis of medullary sponge kidney by computed tomographic urography. *Am J Kid Dis* 2007;50:146–50.)

The name of this disorder dates from a 1949 publication by Cacchi and Ricci. It is characterized by tubular dilation of the distal portion of the collecting ducts with numerous associated cysts and diverticula strictly confined to the medullary pyramids. These dilated ducts have the appearance of the bristles on a brush and often are more ectatic and filled with calcifications, giving an appearance suggestive of a bouquet of flowers. In general, classic intravenous urography is more sensitive than CT in detecting mild cases of MSK; however, three-dimensional (3D) volume-rendered imaging acquired during the urographic phase of a multidetector CT urogram can also establish the diagnosis (Fig. 131-27). The current literature suggests that single-slice helical CT, ultrasonography, and MRI are not able to detect findings specific to MSK. However, CT urography with 3D volume-rendered imaging is comparable to intravenous pyelography (IVP) for the diagnosis of MSK (Maw, 2007).

A significant number of patients with MSK are asymptomatic, and their condition is never diagnosed. As a result, the true incidence of the condition is unknown. Among patients undergoing intravenous urography for various indications, 1 in 200 were found to have MSK (Palubinskas, 1961; Myall, 1970). MSK is more common in calcium stone formers. It is usually regarded as a non-hereditary disease, and the small number of reported cases in children implies that this is an acquired rather than a congenital disease. There has been some recent evidence, however, that some forms of the disease are inherited in an autosomal dominant-type fashion. This evidence supports the hypothesis that MSK is caused by a disruption at the ureteric bud–metanephric blastema or RET/GDNF interface (Gambaro, 2013).

Clinical Features

MSK is usually a benign process, and it may remain asymptomatic and undetected for life. Clinical presentation usually occurs after age 20 years, with the most common presentation being renal colic (50% to 60%), followed by urinary tract infection (20% to 33%) and gross hematuria (10% to 18%) (Kuiper, 1976). The incidence of MSK in stone formers differs widely in the reported series, ranging from 2.6% to 21%. The incidence appears to be higher in female than in male stone formers (Palubinskas, 1961; Lavan et al, 1971; Parks et al, 1982; Sage et al, 1982; Wikstrom et al, 1983; Vagelli et al, 1988; Yendt, 1990). Urinary tract infections, likewise, seem to be more common in female patients with MSK (Parks et al, 1982).

One third to one half of the patients with MSK have hypercalciuria (Ekstrom et al, 1959; Harrison and Rose, 1979; Parks et al, 1982; Yendt, 1990). Incomplete distal renal tubular acidosis may be found in as many as 30% to 40% of these patients (Torres and Grantham, 2008). In the absence of infection, the stones passed by patients with MSK are composed of calcium oxalate, either alone or in combination with calcium phosphate. MSK has also been reported in association with rare congenital anomalies, such as hemihypertrophy, Beckwith-Wiedemann syndrome (macroglossia, omphalocele, and gigantism), Ehler-Danlos syndrome, anodontia, and Caroli disease.

Three different clinical pictures of MSK have been described: the typical form characterized by recurrent calcium nephrolithiasis and a number of concomitant tubular defects, including renal acidosis and metabolic bone disease; an indolent form with no or few renal stones and no tubular defects; and a rare but very severe condition dominated by intractable excruciating renal pain (Gambaro, 2013).

Histopathology

The principal finding is dilated intrapapillary collecting ducts and small medullary cysts, which range in diameter from 1 to 8 mm and give the cross-sectioned kidney the appearance of a sponge. The renal size is usually normal or slightly enlarged. The precalyceal canaliculi ectasia may involve one or more renal papillae in one or both kidneys. The lesions are bilateral in 70% of cases. The cysts are lined by collecting duct epithelium (Bernstein, 1990) and usually communicate with the collecting tubules. The cysts and the dilated collecting ducts may have concretions mostly made of pure apatite (calcium phosphate) and, less frequently, apatite and calcium oxalate (Ekstrom et al, 1959). The cysts contain a yellow-brown fluid and desquamated cells or calcified material.

Diagnosis

The urographic features of the disorder are as follows: (1) enlarged kidneys, sometimes with calcification, particularly in the papillae; (2) elongated papillary tubules or cavities that fill with contrast medium; and (3) papillary contrast blush and persistent medullary opacification (Gedroyc and Saxton, 1988). Calcium deposits within the tubules may appear as renal calculi or nephrocalcinosis.

In rare cases, MSK can mimic the radiographic appearance of ADPKD. In these instances, the liver should be evaluated before a

diagnosis is made. In addition, the absence of family history and a CT showing the absence of cortical cysts help confirm the diagnosis.

When nephrocalcinosis is found, other hypercalciuric states, such as hyperparathyroidism, sarcoidosis, vitamin D intoxication, multiple myeloma, tuberculosis, and milk alkali syndrome, must be ruled out. In these conditions, the calcium deposits are in collecting ducts of normal caliber, whereas in MSK the calcifications occur in dilated ducts (Levine and Grantham, 1990).

Treatment and Prognosis

It is the complications of MSK, calculus formation, and infection that require management. Given the frequent presence of hypercalciuria and hypocitraturia (possibly caused by incomplete renal tubular acidosis), treatment with potassium citrate is effective in reducing the rates of calciuria and stone recurrence (Gambaro, 2013). In addition to liberal fluid intake and a low-sodium diet, **thiazides are effective for lowering hypercalciuria and limiting stone formation.** If thiazides cannot be used, **inorganic phosphates may be appropriate;** however, they should not be used in patients with urinary tract infections caused by urease-producing organisms, because of the risk of struvite stones. **For patients with renal lithiasis, thiazides should be administered even if hypercalciuria is not present.**

Because infections are not unusual in patients with MSK, especially if stones are present, cultures should be obtained frequently, and long-term prophylaxis should be considered in some cases. Infections by coagulase-positive staphylococci are common in patients with stones and should be treated even when the colony count in the cultures is less than 100,000/mL (Yendt, 1990). Repeated investigations for hematuria should be avoided. When stones require surgical therapy, standard procedures, such as extracorporeal lithotripsy and percutaneous nephrolithotomy, may be used.

KEY POINTS: MEDULLARY SPONGE KIDNEY

- MSK is usually a nonheritable condition associated with dilated collecting ducts that appear as bristles on a brush on IVP, and the ducts are sometimes filled with calcifications.
- There are high incidences of renal colic (50% to 60%), urinary tract infections (20% to 33%), gross hematuria (10% to 18%), and hypercalciuria (33%).

SPORADIC GLOMERULOCYSTIC KIDNEY DISEASE

GCKD is a specific entity, but the term has often been used to include all conditions in which there are glomerular cysts, regardless of cause. The term *glomerulocystic* means that cysts of the glomeruli or Bowman space are present diffusely and bilaterally. However, cysts of the glomeruli are present in many forms of renal cystic disease, and they may or may not be the predominant pathology. The specific disease entity, glomerulocystic disease (or "sporadic" glomerulocystic disease), is a nonheritable condition producing bilaterally enlarged kidneys containing small cysts, predominantly of the Bowman space. The clinical significance of this disease process is that it is often **indistinguishable from other conditions in which glomerular cysts are present, namely, autosomal dominant polycystic disease, familial hypoplastic glomerulocystic disease, and juvenile NPH.** Characteristically, with sporadic GCKD, no other family members are affected and no associated anomalies are typically present.

ACQUIRED RENAL CYSTIC DISEASE

ARCD, also known as *acquired cystic kidney disease* (ACKD), is defined as bilateral cystic renal change in patients with ESRD from

causes other than inherited renal cystic disease. A minimum of three cysts in each kidney is required for diagnosis. This disease entity was first described in 1977 in **patients receiving hemodialysis; however, it soon became apparent that the disorder is almost as common in patients receiving peritoneal dialysis** (Dunhill et al, 1977; Thomson et al, 1986). It is now known that dialysis is not a prerequisite of ARCD, and it is likely that the uremic state causes the pathologic changes seen; dialysis merely prolongs patient survival and the amount of time available for the cystic changes to occur (Fisher and Horvath, 1972; Ishikawa et al, 1980; Kutcher et al, 1983; Miller et al, 1989; Truong et al, 2003).

The prevalence and severity of this disease increase with the duration of azotemia and the subsequent need for dialysis. Acquired cysts are found in roughly 10% of patients with ESRD before dialysis. The incidence increases to 44% within 3 years after initiation of dialysis, to 60% at 5 years after initiation of dialysis, and to greater than 90% if the patient is on dialysis for 10 or more years. ARCD is three times more common in men than in women and is generally thought to be unrelated to age or the cause of renal failure. African-Americans and perhaps Japanese are more prone than Americans of European descent to develop ARCD (Reichard et al, 1998). ARCD can occur in children as well (an incidence of approximately 23% has been reported) (Hakim et al, 1994). A successful renal transplant was previously thought to delay or even reverse the cystic changes, but this is not supported by more recent data (Heinz-Peer et al, 1995; Doublet et al, 1997; Kliem et al, 1997).

Etiology

Several etiologic theories have been proposed for ARCD, although the exact cause has not been identified. One theory suggests that tubular obstruction resulting from fibrosis, oxalate crystals, vascular occlusion, or ischemia leads to cyst formation. Various other findings suggest a role for toxins. First, the cysts, adenomas, and carcinomas usually are multiple and bilateral, as are the carcinomas induced experimentally in rats by toxins. Second, there is often a regression of the cysts after successful transplantation (Ishikawa et al, 1983), suggesting that some cystogenic or carcinogenic toxin of uremia is being eliminated by the allograft. Third, if transplantation fails and dialysis is resumed, the cysts return even in chronically rejected transplanted kidneys. Another hypothesis suggests that the accumulation of growth factors, such as epidermal growth factor (EGF), and other stimulatory chemicals (present with uremia) leads to the development of cysts (Bisceglia et al, 2006). Yet another theory suggests that loss of functioning renal tissue leads to the production of renotrophic agents that induce hyperplasia of remaining glomeruli, cyst development, and in extreme cases renal tumors (Harris et al, 1983; Yamamoto et al, 1983).

Clinical Features

Most patients with ARCD are asymptomatic. **The majority of clinical manifestations result from spontaneous bleeding into one or more of the cysts, making the most common presentation loin pain, hematuria, or both conditions. Bleeding occurs in as many as 50% of patients** (Levine, 1996). When significant bleeding occurs, it may cause a subcapsular or retroperitoneal hematoma and may be secondary to renal cysts or to RCC. This bleeding may be complicated by coagulation defects induced by uremia or heparinization during dialysis. Other, much less common complications are cyst infection, urolithiasis, and a rapid rise in hematocrit, which is probably related to increased renal synthesis of erythropoietin (Shalhoub et al, 1982; Ratcliffe et al, 1983; Mickisch et al, 1984). Patients with microscopic hematuria (more than 5 red blood cells per high-power field), both dialysis patients and transplant recipients, should be radiographically evaluated because of the increased risk of tumor formation in these groups (Kim, 2010).

Renal neoplasms, principally adenomas, occur in 10% of patients receiving chronic hemodialysis, and, when ARCD is present, the

incidence of neoplasms is even higher, ranging from 20% to 25% (Gardner and Evan, 1984; Schwarz, 2007). The overall prevalence of RCC in hemodialysis patients is approximately 1%. Carcinoma is 3 times more likely in the presence of ARCD and 6 times more common in large cystic kidneys than in small cystic kidneys (Torres and Grantham, 2008). Overall, the incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population (Resseguie et al, 1978; Port et al, 1989; Levine et al, 1991; Ishikawa, 1993; Truong et al, 1995).

Compared with the sporadic form, RCC associated with ARCD is characterized by younger patient age, male predominance, frequent multicentricity and bilaterality, and less aggressive behavior (Gronwald et al, 1999; Denton et al, 2002; Truong et al, 2003). Approximately 20% of ARCD-associated RCC metastasizes versus 50% for sporadic RCC. The risk factors for tumor development include male gender, duration of dialysis, and kidney weight, but not type of dialysis. Children on dialysis can also develop RCC, despite its rarity in the general pediatric population. Most tumors (86%) are asymptomatic, and the symptomatic ones are related mostly to bleeding from tumor. Many manifest exclusively as persistent hematuria and are not seen by any available imaging techniques. Nephrectomy is recommended for tumors larger than 3 cm or for smaller ones that are associated with persistent hematuria or rapid growth (Truong et al, 1995; Ishikawa, 2000).

Histopathology

Both kidneys are usually smaller than normal, and the cysts are multiple and bilateral. The cysts develop predominantly in the cortex, although the medulla may be affected, especially later in the disease process (Fig. 131-28). The cysts average 0.5 to 1.0 cm in diameter, but some have been reported to reach 5.0 cm (Miller et al, 1989). Larger cysts, a frequent feature of ADPKD, are rare. The cysts are unilocular and contain clear, straw-colored, or gelatinous fluid, with frequent bleeding and/or neoplastic transformation.

Most cysts are lined by a single layer of epithelium composed of flat nondescript cells, cells with abundant cytoplasm and hyaline droplets, or small cuboidal cells resembling those from distal tubules or collecting ducts. Cysts usually show secondary changes, including luminal deposition of degenerated blood, hemosiderin, or calcium oxalates (Hughson et al, 1986; Ishikawa, 1991; Truong et al, 1995). The nuclei of the epithelial cells in these cases are round and regular, without prominent nucleoli (Hughson et al,

1980). However, some cysts (atypical or hyperplastic) are lined by epithelial cells with larger, irregular nuclei that contain prominent nucleoli and may show mitotic activity. This hyperplastic lining is thought by some to be a precursor of renal tumors. Moreover, some hyperplastic cysts have papillary projections, and to some observers the distinction between cyst and neoplasm becomes blurred when papillary hyperplasia predominates.

Differentiating renal tumors into adenomas and carcinomas is arbitrary at times. Most renal nodules that are smaller than 1 cm in diameter are adenomas, and most that are larger than 3 cm in diameter are carcinomas. Tumors between 1 and 3 cm in diameter must be considered equivocal. It is not clear whether renal adenomas undergo malignant transformation. It is believed that atypical hyperplastic epithelium occurs even without cyst formation and that these cells are the precursors of both atypical cysts and adenomas (Hughson et al, 1986). It is thus possible that either hyperplastic cysts or adenomas can become RCCs. Therefore one must not ignore the native kidney left in situ during a renal transplantation. Hyperplastic cyst epithelium has also been considered a possible precursor of RCC in other cystic diseases (VHL disease and tuberous sclerosis) (Fayemi and Ali, 1980).

Evaluation

Ultrasonography is the modality most commonly used to diagnose and monitor patients with ARCD. CT and MRI identify more cysts, and MRI is probably better at demonstrating and characterizing small lesions in particular (Heinz-Peer et al, 1998). Ultrasonography usually shows small, hyperechoic kidneys with cysts of various sizes. Cyst wall calcification may be visible, but it is more readily seen on CT. CT with and without contrast is better for distinguishing kidneys with a few simple cysts from those with multiple acquired cysts and is the most useful for detecting neoplasms. In patients with ESRD not yet on dialysis, however, the use of CT contrast should be avoided for fear of causing further deterioration of renal function. Ultrasonography and MRI with gadolinium enhancement are better alternatives to contrast-enhanced CT in these patients. A word of caution, however: Nephrogenic systemic fibrosis (NSF) is a rare but serious and life-threatening disorder observed in patients with renal impairment and is associated with the infusion of gadolinium as an MRI contrast agent in patients with ESRD. Caution should be used when using gadolinium in these patients.

In uremic patients with fever, one should consider the diagnosis of ARCD and the possibility of an infected cyst (Bonai et al, 1987). Infection should be suspected if ultrasonographic examination shows internal echoes or a thickened wall. Cyst puncture can be used to confirm the diagnosis and to identify the infecting microorganism. CT examination may identify cyst wall thickening in patients with infection.

In the differential diagnosis of ARCD, the etiology of the renal failure must be considered and, in particular, the possibility of ADPKD. Usually, patients with ARCD have smaller kidneys and smaller cysts and are free of the extrarenal manifestations of ADPKD. In patients receiving hemodialysis, kidneys affected by ARCD usually are smaller than 300 g; ADPKD kidneys usually are larger than 800 g (Feiner et al, 1981).

Treatment

Bleeding episodes are often treated conservatively with bed rest and symptom control. Persistent bleeding and pain, however, may require nephrectomy or renal embolization. If heparinization is associated with hematuria during hemodialysis, peritoneal dialysis may be substituted. Because the risk of undetected RCC is high in patients with retroperitoneal hemorrhage, nephrectomy is recommended when carcinoma cannot be ruled out. If a few larger cysts are associated with flank pain, percutaneous aspiration (with cytologic examination) is a reasonable temporizing measure, because ARCD may regress after successful renal transplantation (Torres and Grantham, 2008). For an infected cyst, percutaneous drainage

Figure 131-28. Bilateral multiple renal cysts and diffuse calcification in enlarged kidneys in a patient undergoing chronic hemodialysis. The findings simulate those of ADPKD. However, cystic disease was not the cause of the uremia, and the diagnosis of acquired renal cystic disease was made. (Courtesy D. Gordon, MD.)

may be effective. When it is not, surgical drainage or nephrectomy should be considered.

Although small renal tumors may metastasize, it is known that those smaller than 3.0 cm in diameter rarely do so (Bell, 1935; Talamo and Shonnard, 1980). Thus it is currently recommended that renal masses larger than 3 cm detected in patients with ACKD be treated by surgical excision. For tumors smaller than 3 cm, some advise nephrectomy for the acceptable surgical candidate, whereas others recommend annual CT follow-up with resection only if the tumors enlarge. Although metastases are statistically less likely to occur from small than from large tumors, small tumor size is not a guarantee against metastasis. Laparoscopic bilateral radical nephrectomy in patients with ESRD, ACKD, and suspicious tumors has been proposed as a more desirable alternative to traditional open surgery (Ghasemian et al, 2005).

It has been recommended that patients who have been receiving hemodialysis for longer than 3 years be screened by ultrasonography and CT and then monitored by ultrasonography every 6 months if the kidneys are without cysts and tumors or by both ultrasonography and CT on the same schedule if cysts or tumors smaller than 2 cm are identified (Sarasin et al, 1995). The benefit of screening in this population continues to be the subject of much debate. It has been proposed that screening be restricted to patients younger than 55 years who have been on dialysis for at least 3 years and are in good general health (Sarasin et al, 1995). Others have suggested that screening of patients should be considered when known risk factors exist, such as prolonged dialysis, presence of ARCD, and male gender (Reichard et al, 1998).

A number of investigators have found that the cysts of ARCD regress after renal transplantation (Ishikawa et al, 1983; Kutcher et al, 1983; Thomson et al, 1986). Therefore it was considered that the incidence of RCC might fall after transplantation as well. Unfortunately, 18% of patients developed new cysts after transplantation, and renal carcinoma can occur in the native kidney 3 to 8 years after transplantation (Ishikawa, 1991; Levine and Gburek, 1994). It appears that the malignant potential of ARCD may persist for many years after transplantation, especially in older transplantation patients and in men (Heinz-Peer et al, 1995). Finally, it must be remembered that immunosuppression in and of itself makes these patients vulnerable to carcinoma. Native kidneys account for 4.5% of all malignancies in renal transplantation recipients (Penn, 1979). After renal transplantation for ESRD, the risk for developing RCC is more than 15-fold increased (Kasiske, 2004). RCCs of native kidneys and RCCs of the allografts can be distinguished, with more than 70% of the tumors occurring in native kidneys (Tsaur, 2010; Klatte, 2011). It also appears that the clinical significance of RCC in patients undergoing chronic hemodialysis must be questioned because in this population, RCCs rarely cause metastases or death. In contrast, renal cancer in the transplant population behaves quite aggressively and warrants aggressive evaluation both before and after renal transplantation (Pope, 1994).

KEY POINTS: ACQUIRED RENAL CYSTIC DISEASE

- ARCD is associated with chronic renal failure and is most often seen in patients on long-term hemodialysis and peritoneal dialysis.
- ARCD consists of hyperplastic renal cysts and frequently adenomas; either can progress to RCC.
- The incidence of renal malignancy in dialysis patients is 5 to 50 times greater than in the general population. If RCC develops, it mostly does so before 10 years of dialysis.
- The cysts usually regress with transplantation. Even when this occurs, there still is some suggestion that the risk of developing RCC still persists, but at a much lower incidence.

CALYCEAL DIVERTICULUM (PYELOGENIC CYST)

A calyceal diverticulum is an outpouching of the collecting system into the corticomedullary region of the kidney, and it usually arises from the fornix of a calyx. It is a transitional epithelial-lined, smooth-walled, spheric cavity that communicates with the pelvicalyceal system by a thin channel or neck, typically in the upper or lower pole. It is sometimes known as a *pyelogenic cyst*, especially if it arises from the renal pelvis. The size of such lesions can range from a few millimeters to several centimeters. Most diverticula are presumed to be congenital; however, similar lesions may occur as a result of blunt renal trauma or obstruction of a calyceal infundibulum. Diverticula are usually asymptomatic but may occasionally develop calculi. The calculi may be a single larger stone or multiple tiny stones. Occasionally, milk of calcium may be present. Passage of a stone through the narrow channel into the calyx may cause pain and hematuria.

Radiographically, these diverticula are seen as a spheric collection of contrast medium adjacent to a papilla on IVP; however, the connecting channel is often too narrow to be demonstrated. On upright films, the urine and contrast media form a fluid level. Calyceal diverticula can also be seen on CT, MRI, and ultrasonography, but the distinction between an obstructed calyx and a renal cyst may be difficult unless contrast is administered (Fig. 131-29).

This entity is discussed in more depth in Chapter 130.

PARAPELVIC AND RENAL SINUS CYSTS

Parapelvic cysts, renal sinus cyst, peripelvic cyst, pelvic cyst, parapelvic lymphatic cysts, hilus cysts, cysts of the renal hilum, and parapelvic lymphangiectasia are all terms used to describe cysts that are adjacent to the renal pelvis or within the hilum. Although some peripelvic cysts are simple cysts that arise from the renal parenchyma and impinge on the renal pelvis, true cysts derived from the renal sinus have no parenchymal cause. Thus the terms *parapelvic* and *peripelvic* are terms better used to describe the location of parenchymal cysts, and the term *renal sinus cyst* more accurately describes all other cysts in the hilum that are not derived from the renal parenchyma but rather from the other structures of the renal sinus, such as arteries, lymphatics, and fat. These are all benign lesions found in 15% to 20% of patients at autopsy. With modern imaging techniques, they can easily be distinguished from more serious lesions of the renal pelvis or renal parenchyma (Fig. 131-30).

The predominant type of renal sinus cyst appears to be a result of dilation of lymphatics; however, the mechanism responsible for these changes is not known. Most often these cysts are multiple, and often they are bilateral. Other renal sinus cysts are caused by fluid replacing adipose tissue in the renal sinus as the kidney becomes affected by local vascular disease and atrophy.

Patients are usually in their fifth or sixth decades and are almost always asymptomatic. These cysts are usually discovered incidentally in the course of evaluation for other conditions, such as urinary tract infections, nephrolithiasis, hypertension, and prostatism. There are rare instances of obstruction of a collecting system from these cysts. Ultrasonography will show multiple echo-free areas in the region of the renal sinus. Differentiation from hydronephrosis may be difficult. A diagnosis of hydronephrosis is established without question when dilated calyces are seen to communicate with a dilated renal pelvis. On CT, renal sinus cysts have the attenuation value of water, and they can often be seen within the renal sinus as they displace the calyces peripherally. On nonenhanced scans, multiple renal sinus cysts resemble a dilated renal pelvis and thus mimic hydronephrosis. Differential diagnosis should include renal sinus lipomatosis (fat density), lymphoma, hemorrhage, and urinoma. The therapeutic approach to renal sinus cysts should be conservative.

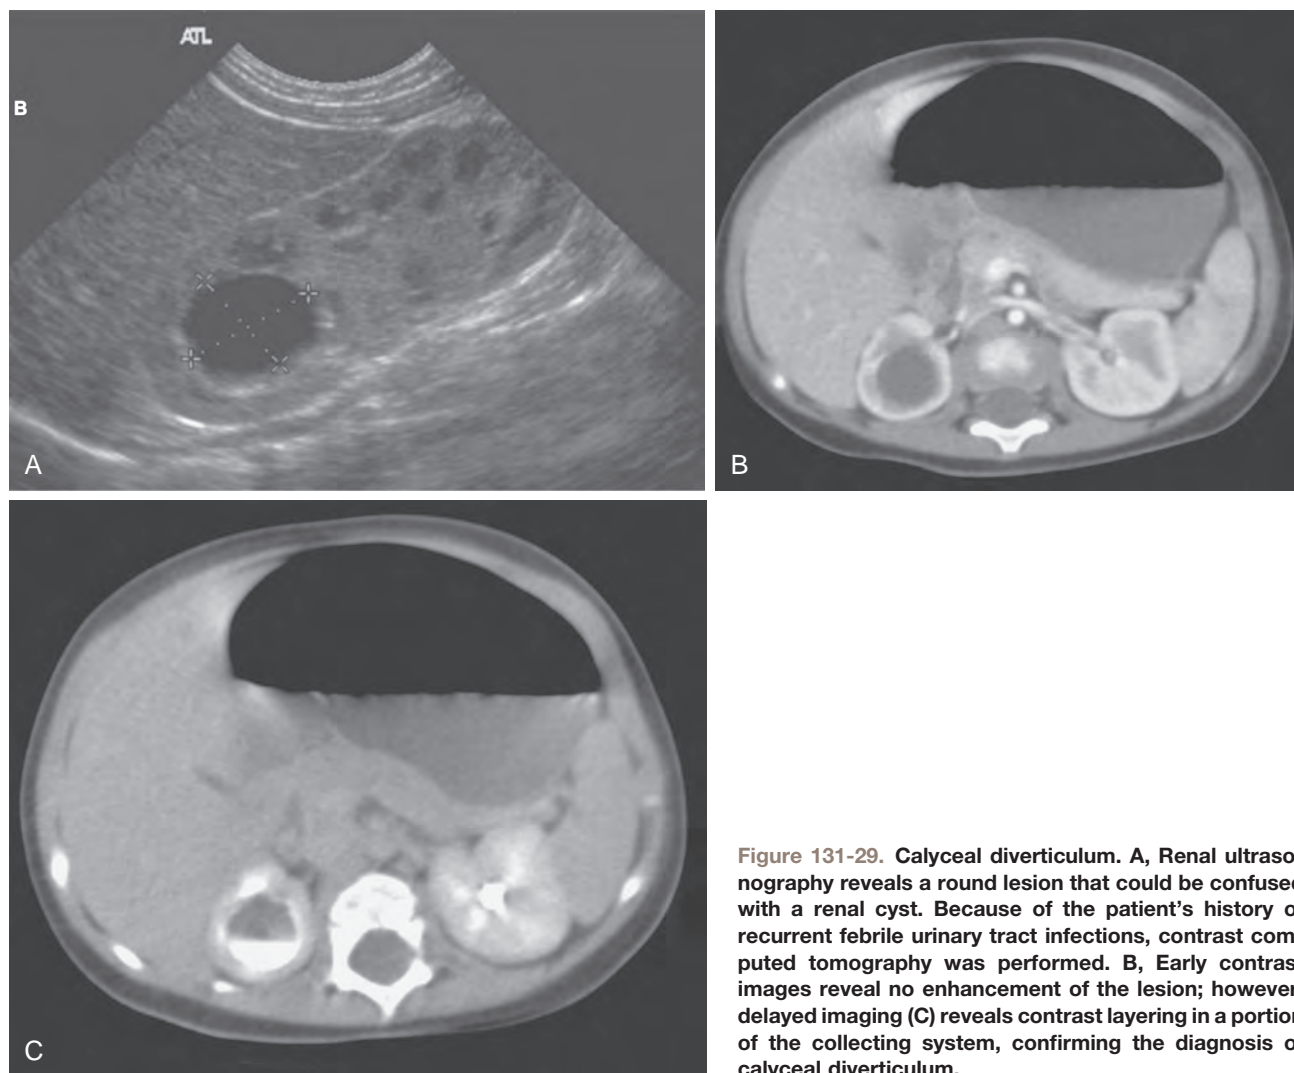

Figure 131-29. Calyceal diverticulum. A, Renal ultrasonography reveals a round lesion that could be confused with a renal cyst. Because of the patient's history of recurrent febrile urinary tract infections, contrast computed tomography was performed. B, Early contrast images reveal no enhancement of the lesion; however, delayed imaging (C) reveals contrast layering in a portion of the collecting system, confirming the diagnosis of calyceal diverticulum.

Figure 131-30. Parapelvic cyst. A, A hypoechoic, well-circumscribed, round focus in the peripelvic region of the kidney. B, There is no delayed enhancement after the administration of intravenous contrast. There is no hydronephrosis or hydroureter. Note contrast within the ureter on the contrasted images.

ACKNOWLEDGMENT

I would like to thank Anthony Kallas Chemaly, MD, fellow in Pediatric Urology at Femme Mère-Enfant Hospital (Lyon, France), for his assistance with factual proofreading.

Clinical Context

Clinical Presentation of Obstruction

Progressive Renal Dysfunction

Definition of Obstruction

Patterns of Congenital Obstructive Nephropathy

Reversal of Congenital Obstruction

Approach to Clinical Cases

Prognosis and Management Strategies

CLINICAL CONTEXT

The spectrum of urinary obstruction in children is one of the most common conditions affecting the urinary tract and it includes substantial health consequences. Obstructive nephrouropathies constitute the single largest entity leading to renal insufficiency in male children younger than 1 year of age, and renal insufficiency is the largest single cause of renal failure needing transplantation, occurring in about 23% of children undergoing transplant (Benfield et al, 2003; Seikaly et al, 2003). A large number of children are affected by lesser degrees of obstruction and may undergo years of clinical monitoring and imaging studies.

The wide spectrum of obstructive changes constitutes one of the major challenges in the clinical management of these conditions in that there is no definitive dividing line between obstruction that warrants intervention and obstruction that does not (Peters, 1995). The presence of an obstructive lesion is readily determined with current imaging, but the criteria for intervention remain controversial. This is largely due to the absence of effective markers of the patterns and progression of obstruction as well as limited information regarding the natural history of differing degrees of obstruction (Chevalier, 2004). We are left with few guideposts along the spectrum of obstruction by which clinical decisions may be made.

This chapter will review the current state of knowledge regarding the pathophysiology of congenital urinary obstruction, how it may be correlated with clinical scenarios, and its distinction from post-natal obstruction. It is anticipated that with increasing understanding of the mechanisms of congenital urinary obstruction, we will become better able to discriminate between children requiring therapeutic interventions from those in whom this would be unnecessary.

CLINICAL PRESENTATION OF OBSTRUCTION

Prenatal ultrasonographic diagnosis has radically altered the clinical presentation of obstructive conditions and today most are detected before birth, and many have no apparent clinical signs. Those with clinical manifestations are often severe obstructive conditions such as posterior urethral valves or massive hydronephrosis. Children are still found with clinical signs of obstruction, usually infection or pain, and rarely hypertension. In the child with obstruction of the entire urinary tract, even when the obstruction is relieved, the functional abnormalities inform us of the effects of obstruction on developing kidneys. Reduced filtration function resulting from glomerular injury can cause a rising serum creatinine concentration, acidosis is due to tubular injury, and nephrogenic diabetes insipidus is secondary to collecting-duct abnormalities. In extreme cases, these may all be present, but on

occasion they are noted in isolation and may persist after relief of the obstruction (Hutcheon et al, 1976). Obstructive hypertension appears to be renin mediated (Riehle and Vaughan, 1981; Urata et al, 1985; Mizuiri et al, 1992) and may be reversible with surgical repair (de Waard et al, 2008).

The pathologic correlates of these functional alterations have been described in the congenitally obstructed kidney to varying degrees (Elder et al, 1995; Stock et al, 1995; Han et al, 1998; Poucell-Hatton et al, 2000; Zhang et al, 2000; Huang et al, 2006). The pathologic changes associated with lesser degrees of obstruction have been less thoroughly investigated, and a spectrum of qualitatively similar alterations has been described. In the absence of overt functional alterations and in unilateral conditions, determining the state of the one affected kidney becomes a clinical challenge. This challenge is often tied to the question of whether surgical intervention is appropriate, and much controversy has emerged from this question. Clinical imaging studies are currently the only widely used modality to make this assessment and their interpretation is variable. The natural history of many conditions in the spectrum of obstruction is not well described, yet it is the essence of the clinical question. It should be clearly seen that the spectrum of obstruction is wide, involves conditions that do not require intervention as well as others that produce profound renal injury, and may change with age and persistence of the obstruction.

PROGRESSIVE RENAL DYSFUNCTION

A major concern regarding obstructive conditions in the urinary tract is the potential for a progressive situation leading to ever-increasing loss of renal function. Progression may be seen in two forms, one with the uncorrected partially obstructive lesion (i.e., ureteropelvic junction obstruction [UPJO]), and the second with the previously obstructed, but corrected obstruction that has produced some degree of renal damage (i.e., posterior urethral valves). In the first, renal function may initially appear intact on imaging tests, yet in time there will be progressive loss of absolute and relative function of the kidney affected by the obstruction. If this were known prospectively, intervention would be appropriate and should be performed early. The challenge is in predicting this situation, and few markers are available to do this. The frequency of progressive deterioration in unilateral asymptomatic obstruction likely ranges from 20% to 40%, but duration of follow-up will affect this rate significantly. Every prospective study of obstructive conditions has documented the potential for progressive loss (Parkhouse et al, 1988; Koff and Campbell, 1992; Palmer et al, 1998; Koff, 2000; Thorup et al, 2003; Ross et al, 2011).

The second situation reflects the fact that the damaged kidney does not have the functional reserve of a normal kidney by which

Figure 132-1. Graph depicting the progressive deterioration in renal function and progression to end-stage renal disease in children with posterior urethral valves. (From Heikkilä J, Holmberg C, Kyllönen L, et al. Long-term risk of end stage renal disease in patient with posterior urethral valves. *J Urol* 2011;186:2392–6.)

it may maintain its absolute function throughout time. These kidneys will demonstrate a steady decline in function with time, and this is usually evident only in bilateral obstruction. The mechanism may be hyperfiltration of remnant renal units and clinically this is most often seen with posterior urethral valves (Parkhouse et al, 1988; Nguyen and Peters, 1999; Heikkilä et al, 2011). These children may show adequate renal function early in life yet demonstrate a delayed and inexorable progression into renal failure in adolescence (Fig. 132-1). Whether earlier intervention would have protected their renal function is uncertain, but that possibility cannot be neglected. Ultimately, specific therapeutic interventions could be targeted toward prevention of this progressive process.

Predictors of ongoing progression of renal injury secondary to either ongoing or previous renal obstruction are of critical importance, yet there are few on which to rely. The most evident predictor is altered absolute renal function as clinically indicated by a creatinine clearance or serum creatinine. This is relatively insensitive in early stages of progression. Radionuclide imaging may be helpful in some cases, but there is no gold standard as to the best interpretation of potentially progressive disease. Urinary biomarkers have been extensively investigated, yet none are commonly used (Madsen et al, 2011).

KEY POINTS: CLINICAL CONTEXT

- Obstruction is the single largest entity leading to renal insufficiency in boys younger than 1 year and is the largest single cause of renal failure requiring transplantation.
- Progression of obstructive renal dysfunction may be seen in two forms, one with an uncorrected, partially obstructive lesion and the other with a previously obstructed but corrected lesion that has produced some degree of renal damage.
- The second situation reflects the fact that the damaged kidney does not have the functional reserve of a normal kidney by which it may maintain its absolute function with time.
- Elevated creatinine indicates altered absolute renal function but is relatively insensitive in the early stages of progression.

DEFINITION OF OBSTRUCTION

Although it may not be difficult to diagnose the potentially obstructed urinary tract, usually by ultrasonographic identification of hydronephrosis, the determination of whether this particular

condition requires surgical intervention to protect renal function and development is much more difficult. The frequently quoted definition of congenital obstruction (Koff, 1987), that of “a condition producing a restriction of urinary flow that will lead to deterioration in renal function,” seems too limited. In the growing child, renal function is expected to increase significantly, initially in excess of body mass and subsequently in parallel to it. If this increase in function does not occur, renal functional potential is lost, which may be of greater consequence than losing absolute function. Therefore the impairment of renal functional development should be considered as a determinant of obstruction that warrants intervention (Peters, 1995).

If this is the case, then an obstructive or hydronephrotic condition that has already resulted in less than normal function should be considered as being likely obstructive and warranting intervention. The child with significant hydronephrosis, with a kidney contributing significantly less than the anticipated 50% on a radionuclide renal scan, has already suffered an impairment of functional potential and should perhaps be considered as having sufficient obstruction to warrant intervention to limit further impairment. The ability to recover function that has not yet been achieved is unpredictable, however.

A critical element of congenital obstructive uropathy (COU) is the recognition that it is distinct from acquired obstruction in the mature animal (or mature kidney). The fact that obstruction develops while the kidney is in the process of formation creates an entirely different paradigm for COU as compared to obstruction of the mature kidney (Peters, 1997). The patterns of renal development are affected by obstruction and this produces the ultimate functional effects. The mechanisms for these alterations are therefore wholly distinct from mature obstruction. Although there is likely to be some overlap in the critical mechanisms of change, many mechanisms will be different. It cannot be assumed that the principles relevant to mature obstruction are applicable to congenital obstruction. This will clearly impact our interpretation of experimental data in the postnatal and mature animal, as well as the selection and application of experimental systems.

One of the frustrations in the management of clinical congenital obstruction is the dichotomy between therapeutic options, which are currently limited to either observation or surgery. Although the surgical options have expanded somewhat, the large gap between these divergent options creates a great deal of tension in the minds of the patient and family, as well as in physicians. The absence of any medical or pharmacologic therapy to ameliorate or prevent the complications of obstruction has been a major factor in the controversy between those who choose to correct a problem and those who believe it is better to await spontaneous resolution or unambiguous evidence of obstructive injury. The horizon holds promise for medical therapies that might prevent renal injury in various ways, but it will be essential to understand more completely the nature of COU to permit such specific treatment.

PATTERNS OF CONGENITAL OBSTRUCTIVE NEPHROPATHY

General Observations

In an attempt to understand the pathophysiology of COU, examination of obstructed renal tissues has shown disorganization of structure with primitive forms of renal tissues, pathologically defined as dysplasia. Although there is not universal agreement regarding the definition of dysplasia, evidence of altered renal development in association with obstruction is frequently reported (Bernstein, 1971; Matsell, 1998; Tarantal et al, 2001; Matsell and Tarantal, 2002; Matsell et al, 2002). Dysplasia is often considered an embryonic process that is irreversible, yet this is not proven. It is clear that some dysplasias are a result of very early abnormalities of renal development (Winyard and Chitty, 2008) and are unrelated to obstruction, but it is equally clear that obstructive processes can produce dysplasia. Whether there are subtle differences between

these patterns is unclear, but it should not be difficult to understand that several underlying etiologies may produce similar outcomes when renal developmental patterns are disrupted.

In some cases, however, usually in lesser degrees of obstruction, there is no dysplasia (Bonsib, 1998; Zhang et al, 2000). In such cases, the mechanisms of obstructive effect may be similar but to a lesser degree, or they may be qualitatively very different. It is important to recognize the variability of the patterns of response to obstruction.

If obstruction can produce dysplasia or abnormal developmental patterns, the particular mechanisms of obstructive effects may be identifiable. These include the fundamental processes of renal development, the character of which may provide insights into the critical mechanisms of obstructive nephropathy. **Development is the controlled process of growth and differentiation of tissues in the formation of an organ or tissue. The factors that regulate these processes are likely targets of obstructive effects.**

Structural alterations with obstruction are obviously evident with hydronephrosis, but this is largely a distortion of normal architecture and relative alterations in the amounts of elements of renal tissues. There may be subtle changes, however, that are functionally important. Other alterations include fibrosis and increased interstitial tissues, as well as the presence of abnormal tubules and glomeruli. The normal layered organization of the kidney with the cortical and medullary areas with inner and outer stripes is often distorted or absent (Zhang et al, 2000). Less obvious will be changes in the differentiation of the individual renal cell types that make up the nephron (Huang et al, 2006). Cells are unlikely to perform their normal functions, including communicating with neighboring cells in an integrated fashion. Function will therefore be disrupted.

Closely tied with these altered patterns of structure are distortions of normal growth regulation with either increased or decreased growth of specific structures. In some cases, obstructed kidneys are markedly smaller than normal, and in a developmental context this does not represent atrophy but rather hypoplasia. The distinction is important in that renal tissue mass has not been lost, but has never been formed. This is growth failure, not atrophy, and the mechanisms are likely distinct.

These observations are supported by both clinical and experimental work. Several biopsy studies have shown patterns indicative of altered differentiation and growth in various levels of obstruction, including both upper (UPJO) (Elder et al, 1995; Stock et al, 1995; Zhang et al, 2000; Huang et al, 2006) and lower (posterior urethral valves) (Poucell-Hatton et al, 2000; Haecker et al, 2002). These variations are not well explained, and correlation with clinical parameters is often imperfect. Experimental studies, however, have shown similarly that obstruction during development will produce changes in patterns of renal differentiation and in growth regulation (Beck, 1971; Steinhardt et al, 1988; Gonzalez et al, 1990; Peters et al, 1992; Wen et al, 2002; Cachat et al, 2003; Mure et al, 2006b). These can be seen to vary depending on the time of onset in experimental models, as well as the severity of obstruction (Fig. 132-2) (Chevalier et al, 1988, 1999c; Thornhill et al, 2005; Klein et al, 2011a; Truong et al, 2011). The latter is difficult to measure accurately. The validity of any of these model systems must be considered conditional, however, until we have more definite correlations. Nonetheless it is clear that induced obstruction can produce such severe abnormalities of differentiation as to be considered dysplasia and it can produce clear disruptions of growth regulation (Peters et al, 1992). It is therefore reasonable to examine the specific patterns observed and the potential mechanisms of those changes, all of which are likely contributing factors in the development of obstructive nephropathy.

Patterns of Effect

The effects of obstruction on the developing kidney may be summarized as producing alterations in the regulation of growth, tissue differentiation, extracellular matrix (ECM) and fibrosis, and in altering the functional integration of the kidney

Figure 132-2. Interval change in kidney weight between 2 and 4 weeks of age in rats subjected to experimental unilateral ureteral obstruction (UUEO) at birth. The sharp drop in weight with decreasing luminal diameter of the ureter suggests a threshold effect on the obstructive effects on renal growth regulation. (Modified from Thornhill BA, Burt LE, Chen C, et al. Variable chronic partial ureteral obstruction in the neonatal rat: a new model of ureteropelvic junction obstruction. *Kidney Int* 2005;67:42–52.)

(Fig. 132-3). The latter is largely a result of the first three major factors and refers to the mechanisms producing vascular, neural, and humoral homeostasis and in the regulation of inflammatory cascades. Understanding the mechanisms by which these systems are dysregulated by obstruction will permit a better understanding of the outcomes of obstruction, which should improve our diagnostic, prognostic, and therapeutic abilities.

KEY POINTS: PATTERNS OF CONGENITAL OBSTRUCTIVE NEPHROPATHY

- Impairment of renal functional development should be considered a determinant of obstruction that warrants intervention.
- COU is distinct from acquired obstruction in a mature kidney.
- Obstructed renal tissues show disorganization of structure with primitive forms of renal tissues, called *dysplasia*.
- Structural alterations caused by obstruction are evident in hydronephrosis as a distortion in normal architecture and relative alterations in the amount of renal tissue elements. Subtle changes are functionally important and include fibrosis and increased interstitial tissue, as well as abnormal tubules and glomeruli.
- The effects of obstruction on the developing kidney vary with the time of onset, as well as the severity of obstruction.
- Obstruction of a developing kidney produces alterations in the regulation of growth, tissue differentiation, and ECM and fibrosis, as well as alterations in functional integration of the kidney.

Growth

Growth regulation is a critical part of development, and the obstructed kidney may evidence impaired or accelerated growth. It is important to recognize that the small, obstructed kidney is not atrophic as might be seen in the adult, but is hypoplastic. The growth it should have experienced never occurred. This can be readily seen by prenatal ultrasound and has been shown repeatedly

experimentally (Peters et al, 1992; Mandell et al, 1994). This seems usually to be a generalized impairment of all parts of the kidney, with both reduced numbers of nephrons as well as smaller nephrons. Differential growth impairment within the nephron segments may be present as well (Cachat et al, 2003; Huang et al, 2006). The functional effects of significant growth impairment are obvious as there are fewer and smaller nephron units. There may be compensatory responses to these changes, and it is difficult to assess their long-term impact. Reduced renal mass can be associated with hypertension as well as reduced filtration function, and loss of tubular mass will affect electrolyte and acid-base homeostasis, as well as water balance.

Growth acceleration can be seen in the larger-than-normal hydronephrotic kidney, although this is difficult to prove in humans, as few of those kidneys are removed. In animal experiments, fetal partial obstruction can increase renal mass (Gobet et al, 1999a; Ayan et al, 2001). This is not seen with dysplastic changes and is not a product of edema, as the total protein and DNA are increased

as well. The factors that predict altered growth appear to be the severity of obstruction and timing of the obstructive effect, although the latter is difficult to ascertain in human situations. The functional consequences of accelerated growth are not known, and this may correlate with the occasional hyperfunction measured on renal scans that is seen in some patients with hydronephrosis (Moon et al, 2003; Maenhout et al, 2005). Compensatory responses to obstruction may not be benign; growth enhancement of the glomeruli occurs in early diabetes and is later associated with glomerular sclerosis.

Growth Regulation of the Kidney. Regulation of renal growth is extremely complex and dynamic throughout development. A variety of growth factors are known to influence kidney growth at various stages of renal development and act at different loci of the nephron. Obstructive conditions have been shown to alter expression of growth-regulatory genes as well as the presence of the proteins coded by these genes (Chevalier, 1996). Table 132-1 lists some of the factors reported as altered in renal obstruction (not all in early

or fetal models) and also shows potentially important mechanistic determinants. Epidermal growth factor (EGF) has been shown to reduce some of the growth effects of obstruction when administered exogenously (Kennedy et al, 1997; Chevalier et al, 1998, 1999a; Wen et al, 2009). Many studies have focused on specific growth factors, but it is evident from the complexity of renal development and growth regulation that the interactions of multiple factors and their signaling pathways will be of greater relevance.

Apoptosis Regulation. A critical component of growth in the developing kidney is apoptosis, which is described as regulated cell death. The early fetal kidney is extremely active in terms of new cell formation as well as turnover (Carr et al, 1995). This permits remodeling during development, as well as providing a control system over unregulated growth. Small increases in the rate of apoptosis, even with normal ongoing growth, would lead to significant reductions in renal mass with time. The role of apoptosis in congenital obstruction has become more firmly established in recent years, including cellular patterns characteristic of apoptosis and enhanced expression of apoptosis-regulating molecules (Yang et al, 2001b; Yoo et al, 2006; Eskild-Jensen et al, 2007a; Campbell et al, 2008; Klein et al, 2011a). The changes may be seen heterogeneously, and the precise means by which these alterations occur remains incompletely defined, although apoptotic activity is regulated by cytokines (Cohen et al, 2007; Manucha et al, 2007; Campbell et al, 2008; Manucha and Valles, 2012) as well as mechanical factors (Nguyen et al, 2000; Hsieh and Nguyen, 2005). Inappropriate apoptosis may also be related to interstitial fibrosis as well (Docherty et al, 2006a). An important aspect of understanding the role of apoptosis in congenital obstruction is that the mediators may be measurable in the urine or blood, and they may permit therapeutic manipulation (Mizuguchi et al, 2008).

Differentiation

Differentiation is the process of cells attaining specific functional traits to permit specialized functions and organization into tissues, and it is the basis for the many functions of the kidney. Obstruction affects these finely tuned patterns by gross structural disruption as seen in a severely obstructed dysplastic kidney. More subtle effects may require assessment of tubular or glomerular function, but all are a result of altered differentiation. Disruption of differentiation may begin as early as induction of the nephron, or later in development with injury to renal collecting duct cells that regulate urinary concentrating ability. Some of these changes may be reversible, but it is usually presumed that many are not, in that some cells will undergo terminal differentiation, and if that does not occur at a particular time in development, there will not be another opportunity for it to occur. Disruption of normal differentiation of renal elements is unique to congenital obstruction, and it does not occur in a major way in adult obstruction. Abnormal epithelial-to-mesenchymal transition (EMT) is one alteration in differentiation that does occur in the adult and it can be reversible (Hay and Zuk, 1995; Yang et al, 2005; Docherty et al, 2006b; Forino et al, 2006; Higgins et al, 2007; Ivanova et al, 2008). A variety of mediators of EMT have been described, including transforming growth factor- β (TGF- β), plasminogen (Zhang et al, 2007), and leukocytes (Lange-Sperandio et al, 2007), as well as inhibitors such as hepatocyte growth factor (HGF) (Yang et al, 2005) (Fig. 132-4). EMT is likely to be an important factor in fetal obstruction as well, although little is known about its role. Most adult cells may be injured and lose their differentiated capacity, but the cell types rarely change their behavior after they are differentiated. Understanding the patterns of altered differentiation and its regulators is critical to understanding congenital obstructive nephropathy.

Induction Process. Renal differentiation begins with induction and from then on is exquisitely sensitive to various outside effects that may disrupt the normal sequence of cellular changes that occurs in the development of a kidney. When these changes may be disturbed by obstruction is unclear, but it can be presumed that some of the variation in the spectrum of obstruction is a result of different times of onset of the obstructive effect and also of different

degrees of severity. The pattern of effect is likely to reflect the time of onset and to be reflected in the number of nephron generations and the degree of dysplastic transformation. Controversy remains as to whether obstruction can produce dysplasia, and it is often stated that if dysplasia is present, then it was due to abnormal induction and not obstruction. Abnormal induction and nephrogenesis might be produced by various factors, including genetic ones, or might be a result of cellular disruption from mechanical forces with subsequent cellular responses. The study of Maizels and Berman is often cited to indicate that dysplasia in the chick kidney (a mesonephric kidney) was only produced with mechanical disruption of the mesenchyme and not hydronephrosis. It should be noted that the production of "obstruction" in that elegant study was by necessity rather crude, and several of the preparations were not obstructed. It is unclear whether all of the obstructions were to a sufficient degree. It also suggests that mechanical forces can, in fact, disrupt nephronogenesis enough to produce dysplasia and there is no inherent reason to believe that this cannot be a result of obstruction as well. Later mammalian studies in fetal sheep have shown dysplastic changes produced by obstruction (Steinhardt et al, 1988; Peters et al, 1992; Matsell et al, 1996), and this has been shown in rodent studies as well (Thomasson et al, 1970).

The critical determinant of dysplasia in animal studies has been complete obstruction early in gestation. In the fetal sheep, dysplasia was only seen when the obstruction was induced before 50% of gestation (70 days in most sheep species, which have a gestation period from 140 to 145 days). Obstruction induced after that point only produces hydronephrotic changes, albeit severe (Beck, 1971). Partial obstructions produced hydronephrosis only, without apparent disruption of the renal architecture. The reason for this is presumably the altered sensitivity of the developing nephrons to obstructive effects at this point. Alternatively, the particular signaling systems that are active in the early phases of renal development begin to fade with ongoing development. It is possible that the pathways sensitive to obstruction that would inherently alter the pattern of development have run their course of expression and activity by midgestation. The expression of recognized mediators of renal development has been affected in models of fetal obstruction, including WT-1 (Liapis, 2003), Wnt gene family (Nguyen et al, 1999), and PAX2 (Attar et al, 1998; Mure et al, 2006b; Cohen et al, 2007; Fenghua et al, 2009).

One of the histologic hallmarks of renal dysplasia is fibromuscular collars surrounding tubular structures, so-called primitive ducts. These have a characteristic appearance, and the smooth muscle surrounding the tubules stains for α -smooth muscle actin (α -SMA) (Fig. 132-5). This pattern suggests an abnormality in the regulation of EMT (Butt et al, 2007; Baum et al, 2008). The mesenchymal structures of the primitive nephrogenic blastema and the epithelium of the ureteral bud processes interact, and there is differentiation from epithelial phenotypes to mesenchymal phenotypes and the reverse. It is uncertain whether the presence of the primitive tubules suggests persistence of mesenchyme that should have transformed to epithelium, or whether it represents inappropriate epithelial-to-mesenchymal transformation. Understanding the signaling pathways involved in these processes (Roberts et al, 2006; Bani-Hani et al, 2008) will directly impact our understanding of obstructive processes. Persistent expression of α -SMA can be seen in partial obstruction without dysplastic patterns, so this may be important at several levels of severity (Gobet et al, 1999a; Mure et al, 2006b). TGF- β 1, linking these two proteins to growth as well as to fibrotic changes, regulates α -SMA expression.

Development of the glomerulus is a tightly regulated process that involves interaction of the mesenchyme and epithelium with a very specific pattern of growth and formation of intermediate structures such as the S-shaped body. In general, primitive glomeruli are not evident in obstructive changes, but markedly abnormal glomeruli are seen as well as hypoplastic glomerular structures (Matsell et al, 2002). In some cases, glomeruli may be enlarged in obstruction, suggestive of the changes seen in hyperfiltration that lead to glomerulosclerosis. Dissociation of the glomerulus from the tubules can be seen in early neonatal rodent obstruction (Thornhill

Figure 132-4. Renal cellular interactions in obstructive nephropathy. The interstitium is infiltrated by monocytes, which are “classically” activated to macrophages that release cytokines such as transforming growth factor- β 1 (TGF- β 1) and tumor necrosis factor- α (TNF- α). In turn, TGF- β 1 promotes a phenotypic response of tubular epithelial cells either to undergo apoptosis (leading to tubular atrophy) or to undergo epithelial-to-mesenchymal transition (EMT), becoming fibroblasts that migrate to the interstitium. Angiotensin II (ANG II), produced by the activation of monocytes, stimulates the production of nuclear factor- κ B (NF- κ B), which leads to the recruitment of more macrophages, as well as to the production of reactive oxygen species (ROS), which aggravates renal tubular injury. In contrast, alternatively activated macrophages can enhance tubular cell survival and proliferation. Endothelial cells can undergo endothelial-to-mesenchymal transition (EndMT) or apoptosis, which leads to capillary loss and to secondary renal ischemia and hypoxia. Resident pericytes and infiltrating hematopoietic stem cells can also differentiate into fibroblasts. Under the stimulus of cytokines such as TGF- β 1 produced by macrophages or other cells, fibroblasts synthesize stress fibers and undergo further differentiation to become myofibroblasts. The myofibroblasts are contractile and augment the deposition of extracellular matrix (ECM), leading to progressive interstitial fibrosis. This process is augmented by a decrease in ECM degradation, mediated by plasminogen activator-inhibitor-1 (PAI-1) and tissue-type plasminogen activator (tPA). (From Chevalier RL, Forbes MS, Thornhill BA. Ureteral obstruction as a model of renal interstitial fibrosis and obstructive nephropathy. *Kidney Int* 2009;75:1145–52.)

et al, 2007), suggesting severe disruption of the developmental program.

Fibrosis

A universal characteristic of obstructive nephropathy appears to be renal fibrosis, although it is a nonspecific pattern seen in a variety of pathologic conditions affecting the kidney (Eddy, 2000; Klein et al, 2011b). It is seen as infiltration of the interstitium with abnormal amounts of ECM, including collagens, fibronectin, and other connective tissue proteins. Their presence disrupts the

normal interconnections between cells that permit functional integration of the renal tissues. Tubular cells may be disrupted and inadequately regulated. Cell:cell signaling by direct connection or paracrine messengers may be disrupted. Tissue oxygenation may be impaired. Fibrosis is a histopathologic hallmark of many renal diseases.

The ECM is essential to normal function of the kidney as well, in terms of providing structural integrity and contributing to normal signaling systems. When abnormally expressed, however, this matrix becomes detrimental. ECM homeostasis is a complex balance of synthesis and breakdown. Synthetic regulation is controlled by

Figure 132-5. Histologic view of normal and obstructed full-term sheep showing the abnormal structural pattern of the kidney, increased interstitial fibrosis and cells, as well as abnormally persistent α -smooth muscle actin (brown stain). (From Gobet, Bleakley J, Cisek L, et al. Fetal partial urethral obstruction causes renal fibrosis and is associated with proteolytic imbalance. *J Urol* 1999;162:854–60.)

KEY POINTS: GROWTH AND DIFFERENTIATION

- The effects of growth impairment include fewer nephron units and delayed nephron maturation.
- Obstructive conditions have been shown to alter the expression of growth-regulating genes, as well as the presence of proteins coded by these genes.
- Congenital obstruction increases apoptosis and cellular patterns characteristic of apoptosis, with enhanced expression of apoptosis-regulating molecules.
- The ultimate cellular effects of such stimuli, however, depend on the summation of competing pro-apoptotic signals and antiapoptotic signals, as well as growth stimulation.
- Alteration in the differentiation of cells is unique to congenital obstruction and does not occur in a major way in adult obstruction.
- The critical determinant of dysplasia in animal studies has been complete obstruction early in gestation.

various mechanisms, including growth factors and signaling systems that are just recently being discerned. Mechanical forces contribute to these signals in various conditions, including hypertension and hydronephrosis. ECM breakdown is tightly regulated and represents the product of degradative enzymes, the matrix metalloproteinases (MMPs), and their endogenous inhibitors, the tissue inhibitors of metalloproteinases (TIMPs). This product is the proteolytic balance and is regulated by various cytokines, hormones, and mechanical forces. This balance has been studied vigorously in renal disease and to a limited degree in congenital obstruction (Engelmyer et al, 1995; Ayan et al, 2001; Mure et al, 2006b). In a neonatal murine model of partial obstruction, the degree of fibrosis and contralateral hypertrophy did not correlate with the degree of hydronephrosis in

the affected kidney (Botto et al, 2011). The interaction of these systems is complex, and various compensatory pathways are likely to be present (Kim et al, 2001; Chevalier et al, 2009).

Oxidative stress in the developing kidney is a probable contributor to both fibrotic and inflammatory pathways in obstructive uropathy. The ability of the immature kidney to mount an appropriate response to increased oxidative stress may define the degree of functional and developmental impairment suffered (Manucha and Valles, 2008; Rinaldi Tosi et al, 2010; Chevalier et al, 2014).

Modulation of renal fibrosis may be a significant potential target for managing obstructive nephropathy, but the delicate balance of these factors needs to be understood to a greater degree than it is at present (Eddy, 2005).

Evidence and Patterns

Increased interstitial connective tissue is a hallmark of various renal pathologic processes (Eddy, 1996), including obstruction. Although it is unclear whether the mechanisms of fibrotic change are universal, they are believed to interfere with intercellular signaling and therefore with functional integration (Fig. 132-6). The most likely causes of excessive connective tissue include abnormal accumulation resulting from imbalance of synthesis and breakdown. This condition may also represent abnormal inductive signaling that produces excessive conversion of epithelium to mesenchymal tissue and connective tissues that accompany this (Bascands and Schanstra, 2005; Burns et al, 2007; Zhang et al, 2007). These processes may be normal developmental sequences that persist because of the obstructive effect.

Abnormal accumulation may simply represent excessive synthesis with no change in ECM breakdown. Increased collagen synthesis has been shown by upregulation of collagen gene expression in obstructive models (Liapis et al, 1994; Fu et al, 2006). Collagen synthesis is regulated in part by various cytokines, including TGF- β and the renin-angiotensin system (RAS). Reduced fibrosis may be

Nephron segment cytokines

seen when angiotensinogen activity is downregulated in an obstructed system (Fern et al, 1999; Kellner et al, 2006). Similar approaches have been demonstrated in nonobstructive fibrosis as well.

The role of TGF-β is complex and context dependent, yet inhibition of activity will produce less fibrosis as well (Isaka et al, 2000; Miyajima et al, 2000; El Chaar et al, 2007). There is evidence that TGF-β interacts and regulates the activity of the RAS, as well as regulating cellular growth dynamics. Fetal obstruction induces increased expression of TGF-β1 (Medjebeur et al, 1997; Ayan et al, 2001; Yang et al, 2001a). Upregulation of the principal TGF-β receptors, TGF-βRI and RII, have been demonstrated in ureteral obstruction in fetal sheep (Yang et al, 2001a). As reviewed earlier, TGF-β1 regulates EMT, thereby contributing to renal dysplasia (Yang et al, 2000). There is considerable interest in the role of TGF-β1 in promoting EMT of differentiated renal tubular epithelial cells in response to chronic ureteral obstruction. As shown in Figure 132-4, renal interstitial fibroblasts, through transformation to myofibroblasts, play a pivotal role in the deposition of ECM in a hydronephrotic kidney. TGF-β1 has also been shown to play a role in glomerular response to injury, because receptor inhibition protects glomerular integrity in the obstructed neonatal mouse model (Galarreta et al, 2013).

There is growing evidence that in addition to proliferation of resident interstitial fibroblasts and transformation of hematopoietic

stem cells, renal tubular epithelial cells can undergo EMT and migrate to the interstitium to contribute to the pool of fibroblasts (Iwano et al, 2002). TGF-β1 regulates many of the steps involved in the transformation of tubular epithelial cells; these steps include loss of cell adhesion, expression of α-SMA, disruption of tubular basement membrane, and cell migration to the interstitium (Liu, 2004). Signaling by TGF-β1 is mediated in part by Smads, which are both profibrotic (Smad2 and Smad3) and inhibitory (Smad7). Thus targeted deletion of Smad3 reduces apoptosis and fibrosis in mice with ureteral obstruction, whereas gene therapy with Smad7 also reduces fibrosis (Lan et al, 2003; Sato et al, 2003). TGF-β1 also acts through downregulation of transcriptional corepressors of the Smads: SnoN and Ski (Yang et al, 2003b). In contrast, HGF blocks EMT by blocking Smad2 and Smad3, and gene therapy with HGF reduces fibrosis in rats with ureteral obstruction (Gao et al, 2002; Yang and Liu, 2003). HGF also acts by upregulating the Smad corepressors SnoN and Ski, countering the action of TGF-β1 (Yang et al, 2005). These complex networks of counterbalancing factors provide many potential opportunities for therapeutic intervention to prevent the progression—or even promote the reversal—of interstitial fibrosis resulting from obstructive nephropathy (Fogo, 2003).

Nitric oxide (NO) was also shown to regulate the development of obstructive fibrosis in postnatal animals and it might play a similar role prenatally (Huang et al, 2000; Felsen et al, 2003;

Manucha and Valles, 2008; Yoo et al, 2010). Increased NO generation reduces the degree of interstitial fibrosis (Ito et al, 2004), and, in animals without the gene to produce NO synthase, unilateral ureteral obstruction (UUO) produces a greater degree of fibrosis than in those animals with this enzyme intact (Hochberg et al, 2000). Data suggest a greater potential role for NO derived from endothelial nitric oxide synthase (eNOS) than inducible nitric oxide synthase (iNOS) (Huang et al, 2000; Chang et al, 2002).

Hypoxia may be a factor in the development of tissue fibrosis as well, in response to induction of hypoxia-inducible factor-1 (HIF-1) and hypoxia-inducible factor-2 (HIF-2) (Higgins et al, 2008). In vitro stimulation of renal epithelia with HIF-1 increases EMT, which is known to induce fibrosis. Genetic models that do not express HIF-1 α develop less fibrosis and inflammatory infiltration in response to ureteral obstruction in postnatal models (Higgins et al, 2007). The role in prenatal obstruction remains undefined, but it is potentially relevant.

Altered regulation of ECM breakdown, the proteolytic balance, is a potential mechanism for interstitial fibrosis of obstruction as well, although this is less explored. Connective tissue breakdown is controlled by the MMPs, of which there are at least 15 having specific activity toward particular connective tissue proteins. MMP-1, for instance, is a collagenase (Pardo and Selman, 2005), whereas MMP-2 specifically degrades gelatin. Their expression and activity are both subject to close regulation, as this is crucial to appropriate ECM homeostasis. Too much activity will degrade the tissues, whereas too little permits accumulation of abnormal amounts of ECM. These pathologic alterations have been described in a variety of disease states, including arthritis and pulmonary fibrosis (Corbel et al, 2002; Vincenti and Brinckerhoff, 2002). One of the means by which their activity is regulated is through endogenous TIMPs. These are less varied and may have less specific activity over the MMPs in their environment, and they serve to check the degradative activity of the MMPs. Their expression and activity are closely regulated and their net activity is the proteolytic balance. The role of the proteolytic balance in a wide variety of disease states has been the subject of active research (Diamond et al, 1998; Vincenti, 2001).

Altered activity and regulation of the MMPs and TIMPs have been studied in the kidney (Eddy, 1996) in several conditions, and it is clear that they are important regulators of the state of the ECM. Their expression has been shown in the developing kidney as well and in postnatal obstruction, and they are altered in activity. In prenatal obstruction, increased expression (Ayan et al, 2001; Mure et al, 2006b) and activity (Gobet et al, 1999a) have been shown as well as in congenital reflux-related fibrosis (Gobet et al, 1998). The precise regulators of the MMPs and TIMPs in development and obstruction are not well defined, but they are likely to be an important element in the development of pathologic fibrosis. There is some evidence of regulation by the RAS and TGF- β as well, which opens therapeutic options for the treatment of fibrosis (Diamond et al, 1998; Ding et al, 2005; Bolbrinker et al, 2006; Yang et al, 2007).

Fibrosis is clearly a major component of the pathophysiology of congenital obstruction. Understanding the role and activities of the various components of this system may permit more specific diagnosis through urinary biomarkers reflecting the elements of the system. These elements may also be relevant targets of therapeutic intervention to modulate ECM homeostasis.

KEY POINTS: FIBROSIS

- One of the histologic hallmarks of renal dysplasia is the presence of fibromuscular collars around tubular structures, so-called primitive ducts.
- A universal characteristic of obstructive nephropathy appears to be renal fibrosis.
- Breakdown of ECM is tightly regulated and represents the product of degradative enzymes (MMPs and their endogenous inhibitors [TIMPs]).

Functional Integration

Renal function is regulated at numerous levels, including vascular, neural, and hormonal factors, and inflammatory processes may significantly affect this function. **Congenital obstruction alters both the ongoing functional integration of the kidney as well as the development of the mechanisms that are intrinsic to this regulation. It can change the regulatory mechanisms themselves.** For example, hypertension is well recognized as a potential consequence of obstruction, and it might have effects beyond the kidney. More subtle effects on the normal regulatory systems of the kidney may be more difficult to detect.

Inflammation appears to be a common consequence of obstruction in the postnatal human or animal model. Much attention has been paid to this in acquired obstruction, but it is surprisingly absent in congenital obstruction. Biopsies of human kidneys with obstruction but no history of infection have sparse inflammatory infiltrates (Huang et al, 2006). Models of fetal obstruction show little evidence of inflammation (Peters et al, 1992). The reason for this marked difference is unclear, but it suggests fundamentally distinct mechanisms. It is another indication that congenital obstruction is distinct in many ways from postnatal acquired obstruction.

Vascular. The developing vascular tree plays a critical role in renal development and any disruption could be associated with a wide variety of abnormalities, ranging from lack of development of the glomerulus to aberrant regulation of renal blood flow. Sensitivity to humoral and neural regulation of blood flow may be altered as well, which may be a permanent effect.

Expression of renal renin is increased in the obstructed kidney (el Dahr et al, 1993; Gobet et al, 1999b; Ayan et al, 2001) and decreased in the contralateral. Renin-secreting renal cortical cells appear to be recruited with obstruction as well (Norwood et al, 1994). Expression of receptors for the RAS is altered in specific patterns in neonatal obstruction. AT1, which mediates vasoconstriction (as well as growth alterations) (Chung et al, 1995; Yoo et al, 1998) increases whereas the levels of angiotensin receptor type 2 (AT2), which act in a contrary manner, are decreased. These alterations suggest a role for a local renal RAS in obstruction-mediated vasoconstriction and are independent of the systemic RAS.

Altered sensitivity of both kidneys to renin-mediated vasoconstriction has been shown to occur with unilateral obstruction. Interaction with NO has been seen as important in the regulation of both glomerular and tubular function in early obstruction (Eskild-Jensen et al, 2007b). Following the release of obstruction, sensitivity to angiotensin-II mediated vasoconstriction was reduced in the obstructed kidney but increased in the contralateral (Chevalier and Gomez, 1988). These observations indicate the sensitivity of renal vascular regulation to obstruction as well as the importance of recognizing the interaction of the two developing kidneys. The role of renal counterbalance in obstruction has been recognized, but it has been investigated only to a limited degree. A possible mechanism for these observations is through neural regulation of renin expression (Chevalier and Thornhill, 1995a).

Neural. Renal innervation is an important regulator of vascularity and perfusion and is associated with expression of renin in the kidney (el Dahr et al, 1991). Sympathetic denervation, both mechanical and chemical, has been shown to reduce the expected increase in renin expression in the setting of obstruction (Chevalier and Thornhill, 1995b). A more primitive pattern of renin gene expression appears to persist with congenital obstruction and may cause a persistence of fetal patterns of neural and vascular regulation.

Hormonal. The major hormones regulating renal functional development are in the RAS, and these are significantly affected by COU. This results in a variety of effects, including growth alterations, fibrosis, as well as altered blood flow. The sensitivity of the kidney to elements of the RAS changes during development, presumably to permit transition from a fetal state, with reduced oxygen tension and limited need for renal perfusion, to the postnatal environment. Postnatally, all filtration must be through the

kidneys rather than through the placenta as occurred prenatally. This is thought to be related to the shift in expression of the angiotensin receptors as one aspect of this system. In fetal life, AT2 is predominant in expression, has a vasodilating effect, and may promote growth, whereas AT1 (type 1) is less active until postnatally, which permits regulation of renal perfusion in the postnatal environment (Robillard et al, 1995). Altered developmental regulation of these receptors has been induced with fetal obstruction as well (Gobet et al, 1999b). Activity of the RAS is balanced in the developing kidney by NO, and alterations in this balance have been demonstrated in the developing kidney subjected to obstruction (Bogaert et al, 1996), perhaps explaining the observed preservation of renal blood flow despite ongoing fetal bladder obstruction (Bogaert et al, 1995; Nguyen and Kogan, 1998). In contrast, with complete fetal UO, renal blood flow was not maintained, indicating thresholds of obstructive severity for certain renal responses (Mure et al, 2006a). Targeting these specific alterations may provide information about the impact of obstruction as well as the possibility of therapeutic value (Topcu et al, 2007). Improved diagnostics may be developed if imaging can be linked to hormonal activity that shows distinct patterns in obstruction. For example if COU induces a balance of the RAS that favors the more fetal pattern of receptor subtypes, perfusion renography or imaging coupled with pharmacologic inhibition or stimulation of this system, as in a captopril renogram, might permit identification of this pattern (Bajpai et al, 2002). It is important to recognize that the integrity of the RAS is critical to normal renal development, and inhibition may produce negative effects on normal renal function or might even exacerbate obstructive effects (Coleman et al, 2007).

Aldosterone may be a potentially useful target for therapy, as it has been shown to contribute to cardiac and renal fibrosis in various pathologic situations (Xu et al, 2008; Ku and Campese, 2009; Lea et al, 2009). Inhibition using spironolactone, a receptor antagonist, has been shown experimentally to limit the amount of interstitial fibrosis in a juvenile rodent model of complete obstruction (Trachtman et al, 2004). This raises the potential for therapeutic interventions using familiar pharmacologic tools, yet it also indicates the complexity of the interaction in the kidney's responses to obstruction.

Tubular Function. Although glomerular filtration and renal plasma flow are the most commonly measured elements of renal function, renal tubular function is equally important, yet is often ignored in obstructive uropathy. Tubular function regulates acid-base homeostasis, electrolyte balance, and urinary concentration as well as vitamin D homeostasis. When bilateral, defects in these various functions are major clinical problems. When unilateral, they are often compensated by the contralateral kidney, and are therefore difficult to measure accurately and noninvasively. There are reports of persisting tubular dysfunction in various congenital obstructions (Hutcheon et al, 1976), but it is uncommon for this to be a clinical problem.

Congenital obstruction can be shown experimentally to produce several functional effects on the renal tubules, including acid/base, sodium, and water homeostasis. Specific downregulation of sodium transporters (Norregaard et al, 2005; Eskild-Jensen et al, 2007b) in the tubules as well as reduction in the expression and protein levels of the aquaporins have been demonstrated in neonatal obstruction in rats and juvenile piglets (Frokjaer et al, 1996, 1997, 2003; Jensen et al, 2006). Downregulation of acid-base transporters in the tubular epithelium has been demonstrated in juvenile rats (Wang et al, 2009). Evidence also exists to demonstrate that some of these transporters may also act as signaling systems affecting tubular apoptosis (Manucha et al, 2007). Although a normal contralateral kidney may compensate for these functional defects, limiting the clinical impact of the defects, alterations in urinary levels of these proteins may serve as markers for significant obstructive effects (Madsen et al, 2011).

The mechanisms of injury are likely to be a combination of the effects described earlier, and therapeutic interventions targeted toward those mechanisms may limit tubular dysfunction. Measur-

ing abnormal tubular function may be possible using more sensitive measures and imaging technology.

Inflammatory Mediators

Although inflammatory changes do not appear to be a major factor in early postnatal COU (Misseri et al, 2004), it is likely that they begin to play a greater role with age. It will be necessary to confirm the pattern and role of these factors of COU in humans, as many animal systems demonstrate significant inflammation postnatally, although fetal systems do not (Peters et al, 1992). Human pathologic material has not shown large amounts of inflammation (Huang et al, 2006), except when complicated by infection (Bartoli et al, 2000; Kiratli et al, 2008). If there were a subset of patients with inflammatory changes in the face of obstruction, it would seem an important target for investigation to improve both diagnostic and therapeutic capability (Meldrum et al, 2006, 2007). The various inflammatory cascades that have been investigated postnatally are manipulable pharmacologically and this may permit important therapeutic regulation of renal injury (Cale et al, 2000). Inflammatory mediators such as monocyte chemoattractant protein-1 (MCP-1), tumor necrosis factor- α (TNF- α), regulated on activation normal T cell expressed and secreted (RANTES), and others may be measurable in the urine as well, as has been shown in experimental systems (Crisman et al, 2001; Silverstein et al, 2003; Madsen et al, 2012).

KEY POINTS: FUNCTIONAL INTEGRATION

- Angiotensin is a key modulator of many of the inflammatory responses to ureteral obstruction.
- Expression of renal renin is increased in the obstructed kidney and decreased in the contralateral one. Renin-secreting renal cortical cells appear to be recruited with obstruction as well.
- The activity of the RAS is altered with obstruction, which affects renal functional development by a variety of changes including growth, fibrosis, and blood flow.

REVERSAL OF CONGENITAL OBSTRUCTION

An important element in the understanding of congenital obstruction is the potential for reversal of renal functional and developmental impairment with correction of the obstructive lesion. This is clinically relevant when making decisions regarding the use of intervention either postnatally or prenatally. In the latter, the potential for reversal has great significance in determining whether the risks associated with fetal intervention are warranted. Improvement in function is also important in the expectation of response to relief of obstruction.

In the fetal obstructed kidney, Glick and colleagues showed that the functional salvageability of a unilaterally obstructed kidney was dependent on the duration of obstruction and gestational age (Glick et al, 1984). A direct relationship between progression of nephronogenesis and reversibility can be demonstrated (Edouga et al, 2001; Fenghua et al, 2009). Similar observations have been made in early postnatal models, with the recognition that complete reversal of the damage is seldom achieved (Claesson et al, 1987; Chevalier et al, 1988, 1999b, 2002; Eskild-Jensen et al, 2003; Shi et al, 2004; Dissing et al, 2008; Thornhill and Chevalier, 2012). Mediators of improvement have not been explored. The severity of obstruction is also a critical determinant (Bussieres et al, 1993), but it is challenging to measure in any meaningful way. Biomarkers of salvageability have been developed and were first used clinically in accordance with the work of Glick and Adzick in obstructed fetal sheep (Adzick et al, 1985). From these basic parameters emerged the clinical prognostic factors currently used, with modification, in fetal obstruction (Harrison et al, 1982; Glick et al, 1985). Measures of urinary sodium, chloride, osmolarity, and

calcium have correlated with fetal renal functional potential (Muller et al, 1993; Johnson et al, 1995; Dommergues et al, 2000; Biard et al, 2005). When fetal urine approaches the character of serum, irreversible damage appears to have occurred in the developing kidney. Other markers have been explored in the fetus, including α_1 -microglobulin in amniotic fluid and β_2 -microglobulin in urine and serum (Burghard et al, 1987; Freedman et al, 1997; Nicolini and Spelzini, 2001; Craparo et al, 2007).

The mechanisms of functional recovery may be similar to the mechanisms of injury, but they may also be unique and the potential may exist for enhancing recovery if these mechanisms can be understood and used. In part, the pathway of recovery includes normal developmental pathways that had been impaired because of obstruction (Chevalier et al, 1988). As a consequence of urinary tract obstruction, nephron injury is heterogeneous, with some nephrons undergoing adaptive growth and hyperfiltration and others being destroyed. Thus, 1 month after relief of 5 days of UUU in the neonatal rat, the glomerular filtration rate (GFR) of the postobstructed kidney was normal despite a 40% reduction in the number of glomeruli (Chevalier et al, 1999b). However, 1 year after relief of the obstruction, the GFR of the postobstructed kidney had decreased by 80% (Chevalier et al, 2000). Even though there had been no further loss of nephrons during this interval, the remaining glomeruli had undergone progressive sclerosis (Chevalier et al, 2000). Although relief of temporary UUU did not lead to nephron loss in the adult rat, there was a reduction in glomeruli after relief of temporary UUU in the period immediately following nephrogenesis, as well as during nephrogenesis (Chevalier et al, 2002). This underscores the susceptibility of the developing kidney to obstructive injury not only during nephrogenesis but also during subsequent nephron maturation.

KEY POINTS: REVERSAL OF CONGENITAL RENAL OBSTRUCTION

- The functional salvageability of a unilateral obstructed fetal kidney is dependent on the duration of obstruction and the gestational age.
- Measures of urinary sodium, chloride, osmolarity, and calcium have been correlated with fetal renal functional potential.
- When fetal urine approaches the character of serum, irreversible damage appears to have been done to the developing kidney.

APPROACH TO CLINICAL CASES

General Approach

The clinical challenge of COU reflects the clinical spectrum of the condition itself. A determination must be made as to which patients need intervention to protect renal functional development. Some will clearly need such intervention, whereas many others will do well without. Given the wide spectrum, it is extremely difficult to determine a clinically practical dividing line between those in whom intervention is appropriate and those in whom it is not needed. This question is relevant to the largest number of patients with some form of COU. The ultimate determination of the need for intervention may come as a single diagnostic test, or it might be the determination based on a pattern of change, or the lack thereof, throughout time. In this situation we wish to be sensitive but will accept being less specific. We would rather not miss a large number of patients with COU needing intervention, recognizing that some patients may undergo further evaluation or intervention when they might not have needed it.

The second challenge in COU is with the patients at the extreme end of the spectrum in whom renal functional impairment has already occurred and poses the threat of permanent and progressive

renal insufficiency. In the face of obstruction, what is our best approach to preserve the maximal amount of renal function? Even with successful surgical intervention, we are often confronted with an inexorable progression to renal failure in these children, yet it would seem reasonable to ask if we can prevent renal demise. As yet there has been no clinically applicable approach, but as our understanding of the pathophysiologic mechanisms of COU improves, we may be able to alter specifically the critical components of the system to regulate better the mechanisms affecting renal response to obstruction.

Diagnosis

General Issues

The challenge in diagnosing "obstruction" has been made more difficult because of disagreement regarding the definition of obstruction. Although the concept that obstruction is an "impairment of urine flow that will produce a reduction in function if left uncorrected" is logical, it misses several important elements in the context of congenital obstruction. One is that the developing kidney should be increasing its function, not remaining static. It also does not provide any insight into the interpretation of a kidney that presents with reduced function when diagnosed. Strictly interpreted, this kidney is already affected by having had its normal potential function limited, and by definition it is "obstructed." This interpretation has not been widely used, however, and it is only on prospective follow-up that a decrease from normal is thought to be indicative of "obstruction." A more useful definition might be that any condition that has or will limit ultimate functional potential should be considered as clinically significant obstruction. It should also be recognized that "obstruction" does not mean surgical therapy is required. Obstruction may be mild and clinically insignificant. The exclusion of these patients from the diagnosis of "obstruction" has tended to force people to create convoluted descriptions of hydronephrotic kidneys.

Ultimately a determination of the potential risk to a kidney will have to be made clinically, and a judgment must be made as to whether a particular child would benefit from intervention. It would seem reasonable and cautious to assume that any hydronephrotic kidney is obstructed until proven otherwise and to assess the degree of risk. Understanding the pathologic mechanisms of obstructive nephropathy will permit more specific examination of the kidney to determine its response. It should be the renal response primarily that is used to make the determination of obstructive effect. The fluid dynamics of the upper urinary tract, although obviously relevant to the renal effect, should not be the primary focus. This may explain why many drainage studies, including diuretic renography and pressure-perfusion tests, are imperfect predictors of the renal response. We have seen that the obstructed kidney is undergoing altered growth regulation, abnormal differentiation, and increased fibrosis, all mediated through a variety of molecular, cellular, and renal homeostatic mechanisms. These patterns of change are likely to be reflected in altered expression of proteins and chemicals, which may be assayed in the urine. There may be systemic alterations that are detectable in the blood as well. The search for these biomarkers has been active, yet few have been firmly linked to the pathologic progression of obstructive nephropathy (Chevalier, 2006; Madsen et al, 2011).

Biomarkers

Biomarkers of renal obstruction may reflect the response of the kidney in a direct manner, such as in the expression of growth factors that contribute to fibrosis or are associated with increased apoptosis in renal epithelium. They may also be downstream effects reflecting specific alterations mediated by other cytokines, which in themselves are not directly relevant but are indicative of the level and pattern of the obstructive effect. A broad approach that is emerging uses assessment of changes in overall protein expression in the urine: proteomics. Normal developing kidneys

have an evolving protein fingerprint, which can be defined (Lee et al, 2008) and which is altered with obstruction. If particular elements of the alteration can be identified and associated with clinical outcomes, these patterns may be diagnostic of functionally significant obstruction. Such patterns may reflect a single protein, which may be an element of a response pattern or might be a downstream consequence. It may be that a particular pattern of protein expression that involves several factors will be the best indicator of obstruction (Decramer et al, 2006, 2008; Stodkilde et al, 2013). Such studies will require development in animal systems and validation in the human. It will be necessary to set limits for what is and is not clinically significant “obstruction” and to correlate this with clinical and functional outcomes of relevance. These changes will need to be correlated with histopathologic changes in the developing kidney as well, as our ability to measure some functional alterations remains imperfect.

An alternative approach to diagnosis may be to assess response to stimulus. This is the basis of the captopril renogram, in which radionuclide uptake in the face of obstruction is reduced when the RAS is inhibited by the angiotensin-converting enzyme inhibitor captopril, but is not reduced in the dilated, nonobstructed system (Bajpai et al, 2002). The underlying rationale for this test is that in the obstructed kidney, function is dependent on increased activity of the RAS, as suggested earlier. In reducing the capacity of this system to support function by the administration of captopril, a decrease is detected in the postcaptopril study. The concept is reasonable, but problems with definitions of true “obstruction” continue to thwart its broad applicability. Alternative pharmacologic manipulations are needed to address more specifically one or more functional factors in the potentially obstructed kidney. The production of various cytokines in the face of a stimulus might provide the ability to distinguish the kidney at risk for injury from the kidney not at risk.

At present, we are limited to the conventional imaging modalities of ultrasound, diuretic renography, and an increasing use of magnetic resonance imaging.

Clinical Evaluation

Presentation

The mode of presentation of obstructive uropathy will often determine the clinical management. Those presenting with symptoms will require a careful anatomic and functional assessment that will likely include surgical intervention. Those in the less discrete category are more challenging, including patients with UPJO and ureterovesical junction obstruction (UVJO) who present without symptoms. If posterior urethral valves, ureterocele, or ectopic ureter is detected, even if asymptotically, intervention is almost always appropriate. Very mild versions might be considered candidates for an observational approach if no evidence of bladder or renal dysfunction is present.

Symptomatic presentation of UPJO and UVJO almost always will be managed with surgical intervention. The timing is unpredictable for such a symptom episode to recur, but the likelihood of recurrence is high even though the probability of recurrence has never truly been determined. Infection is uncommon with UPJO, but not with UVJO, and these children can become very ill because of the combination of infection and obstruction. It seems as if the severity of the obstruction may be exacerbated by the reaction to the infection. Marked increases in hydronephrosis have been reported in association with an acute infectious episode, likely resulting from the effect of bacterial toxins (Pais and Retik, 1975). A pattern of apparent aldosterone resistance has been seen in several children with UVJO and urosepsis, manifested by dangerously low serum sodium levels and presumably resulting from transient resistance to aldosterone caused by bacterial endotoxins (Vaid and Lebowitz, 1989; Levin et al, 1991). Subsequent resolution should not falsely suggest an insignificant process.

Stone development is another form of clinical presentation, often with hematuria or pain. Although the two conditions are

linked, it cannot be assumed that a treatable metabolic disorder is not possible (Husmann et al, 1996). Appropriate evaluation is warranted. Conversely, a stone impacted in the UPJ can create the appearance of a congenital UPJO on routine imaging.

The classic presentation of acute episodes of flank pain and nausea because of UPJO is termed Dietl crisis when bilateral (Dietl, 1864). It can more often occur unilaterally and is often thought to be a gastrointestinal disorder with subsequent misdirected evaluation (Alagiri and Polepalle, 2006). These children can present at any age, although the condition is rarely recognized in early childhood. The pattern is often one of increasingly frequent and severe episodes of acute onset abdominal or flank pain with nausea and vomiting. These episodes may last for minutes to several hours and often occur in the evening. Only occasionally is the episode obviously triggered by fluid intake. Some children will report that leaning over a chair can help reduce the discomfort. Little can reduce their discomfort otherwise, yet when the episode has passed, they seem fully recovered. The repetitive and consistent nature of the episodes, particularly with a nonrevealing gastrointestinal workup, should prompt consideration of a renal cause and the obtaining of an ultrasound. Further evaluation with diuretic renography can usually define the etiology (Sparks et al, 2013). Diagnoses given to these episodes before being accurately identified have included abdominal migraines, cyclic vomiting syndrome, food allergies, musculoskeletal problems, and emotional disturbances. In a most extreme example, a girl received ongoing diagnoses of more and more food allergies while her kidney became progressively nonfunctional, which occurred because of an early evaluation that was misinterpreted.

Imaging

To define both the nature and extent of any potentially obstructive condition, it is necessary to obtain an anatomic and functional assessment of the kidneys, ureters, bladder, and urethra. Performing this in a logical sequence will usually permit an appropriately selective workup. The details of the specific imaging tests, their interpretation, and limitations are presented in Chapter 126.

KEY POINTS: APPROACH TO CLINICAL CASES

- Congenital urinary obstruction may best be defined as urinary flow impairment that has limited or may potentially limit normal renal development.
- Not all hydronephrosis represents obstruction that requires surgical correction.
- Biomarkers for renal obstruction should reflect changes in normal development, as well as specific alterations caused by obstruction.
- Although most clinical cases of congenital obstruction are asymptomatic, the condition in children is still detected by pain, a mass, hematuria, and hypertension.

PROGNOSIS AND MANAGEMENT STRATEGIES

The assessment of possible outcomes for an obstructed kidney is important in terms of determining the value of an intervention and in providing a clinical prediction of possible failure of the kidney. These predictions will serve to guide therapy and to assess the risk/benefit balance in treatment. As yet there are few studies to suggest any accuracy either in unilateral obstruction or bilateral obstruction. Use of renal biopsies in obstruction has shown some loose correlations but none that are clinically practical. It is likely that this ability will follow as a result of more accurate diagnostic ability.

Can any of our current incomplete understanding of COU be used in developing a clinical management strategy for these patients? Several factors seem to emerge from the many conflicting and incomplete studies of congenital obstruction. Obstruction can be

very harmful to the developing kidney, to an extent far beyond that seen in the mature kidney. The effects of obstruction may not be reversible because of the alteration of the actual structure and functional characteristics of the kidney, which does not occur in the mature kidney. There seems to be a limited window of time to permit reversal of obstruction and to anticipate clinically relevant recovery of functional potential. It is clear that the developing kidney, as with the mature kidney, is able to compensate in the face of obstruction and to appear as healthy. Yet most biologic compensation mechanisms are ultimately limited in their ability to maintain homeostasis, and these might mask eventual significant functional derangements. The clinical threshold for intervention may therefore be better set lower than in the mature patient.

The response to obstruction in the developing kidney is extremely complex, and multiple factors are involved in various aspects of this response. Although this may seem to be a significant impediment to understanding and clinically managing these problems, it should be seen as providing multiple opportunities to develop biomarkers of these responses that may eventually facilitate our decision making.

It is clear that not all children with dilated kidneys will suffer ill effects from this condition; it is equally evident that the potential for obstructive nephropathy is significant and has severe clinical implications. As our understanding of these conditions and the mechanisms of renal response to obstruction in development improves, determining which kidneys are at risk for developmental impairment will become more accurate.

Ureteropelvic Junction Obstruction

The first part of this chapter will focus on open surgical repair of ureteropelvic junction obstruction (UPJO), including retrocaval ureters, midureteral strictures, and UPJO in duplex systems. Because of the evolving interest in minimally invasive procedures such as laparoscopy, retroperitoneoscopy, and robotic procedures, these procedures also are discussed. The second part will deal with surgery of the congenital megaureter.

URETEROPELVIC JUNCTION OBSTRUCTION

Definition

Hydronephrosis in children, defined by an anteroposterior intrarenal pelvis diameter of 12 mm (Dhillon, 1998), differs from that seen later in life and is not necessarily synonymous with true obstruction. Available diagnostic tools are imprecise, leaving the definition by Koff as the only gold standard prognosticator of obstruction. Koff (1987) defined obstruction as "any restriction to urinary outflow that if left untreated will lead to progressive kidney damage." Working by this definition, indications for surgery are often amassed retrospectively and at the cost of losing irrevocably valuable renal function. In an attempt to circumvent use of such diagnostics, numerous guidelines have been published; however, in the absence of precise diagnostic tools, indications for surgery always will be debatable (Chertin et al, 2006).

Evidence

Obviously there are two entities in UPJO in children. First of all, the prenatally detected hydronephrosis, which, if unilateral, is assessed 5 to 10 days after birth by ultrasonography. This is due to the fact that the kidney in the newborn has to become functional during the first days of life. Indeed, the case is different in bilateral hydronephrosis when infravesical obstruction is suspected, which may require immediate diversion by a suprapubic or urethral catheter.

Clinical Presentation

In many countries antenatal ultrasound scans are offered at approximately 20 weeks of gestation. Of the malformations identified, urogenital anomalies are dominant and dilatations, in the form of hydronephrosis or hydroureteronephrosis, are most common. Postnatal diagnosis is made by ultrasound, incidentally or in conjunction with the workup for a child presenting with urinary tract infections (UTIs). Febrile infections often are sufficiently treated with antibiotics, with only a minority of patients needing nephrostomy tube diversion in the case of concomitant finding of hydronephrosis or hydroureteronephrosis. Most often, the UPJO in newborns and infants is caused by an *intrinsic* narrowing of the UPJ (Fig. 133-1). The typical finding is a narrowed segment of the UPJ with an interruption in the development of the circular muscular fibers. This leads to a functional discontinuity of the muscular contractions and ultimately to insufficient emptying of the renal pelvis. UPJO in childhood and adolescence is often

Megaureter

caused by an accessory vessel to the lower pole of the kidney (Fig. 133-2), with the ureter kinking over the lower pole vessel (Lowe and Marshall, 1984) (*extrinsic*) giving rise to loin pain, nausea, and vomiting. However, it is unclear whether an intrinsic factor in conjunction with a lower pole vessel is the reason for the symptomatic hydronephrosis (Stephens, 1982). Hydronephrosis is more often seen in boys (Williams and Karlaftis, 1966; Kelalis et al, 1971; Johnston et al, 1977; Olsen et al, 2007), especially in the infant and toddler age groups (Robson et al, 1976; Williams and Kenawi 1976; Johnston et al, 1977; Olsen et al, 2007). UPJO predominates on the left side and is bilateral in 10% to 40% (Nixon, 1953; Uson et al, 1968; Robson et al, 1976; Lebowitz and Griscom, 1977; Karnak et al, 2008). There also might be an increased incidence in family members (Cohen et al, 1978).

Secondary Ureteral Pelvic Junction Obstruction

In some cases of high-grade vesicoureteral reflux (VUR) with a tortuous dilated ureter, kinking or narrowing of the UPJ can be present. Whether this resolves spontaneously or needs surgical correction of both the VUR and the UPJO is not always clear (Lebowitz, 1984; Bomalaski et al, 1997). This condition is specific to high-grade reflux, in which surgical correction of the VUR by injectable biomaterials is doubtful; therefore contemplating concomitant reimplantation and dismembered pyeloplasty is discouraged because there are concerns this may compromise ureteral blood supply. Thus a conservative approach or operation in two stages is advisable, despite the lack of convincing evidence.

Lower Pole Ureteral Pelvic Junction Obstruction

In uncommon cases of duplex kidneys, a UPJO of the lower moiety is seen (Privett et al, 1976) (Fig. 133-3). In cases of incomplete duplication a ureteropelvic anastomosis of the upper pole ureter to the lower pole pelvis is possible, either side to side or end to side. In cases of complete duplication a standard dismembered pyeloplasty is done, depending on the function of both the upper and lower moiety and the length of the stenosis (Joseph et al, 1989). A nonfunctioning or minimally functioning moiety (i.e., $\leq 5\%$ to 10% of the overall kidney function on nuclear scan) should prompt partial nephrectomy rather than any attempts at repair.

Associated Anomalies

Congenital renal malformations are commonly seen in association with UPJO. Up to 50% of the affected infants have another urologic abnormality (Uson et al, 1968; Robson et al, 1976; Lebowitz and Griscom, 1977; Lebowitz and Blickman, 1983; McGrath et al, 1987). Contralateral UPJO is the most common anomaly, seen in 10% to 40% of cases, followed by renal dysplasia, multicystic dysplastic kidneys, and renal agenesis (Williams and Karlaftis, 1966; Robson et al, 1976; Williams and Kenawi, 1976). Horseshoe kidneys are rare but are in some cases associated with UPJO, both with a genuine stricture and accessory vessels (Glenn, 1959; Blanc et al, 2014). VATER syndrome (vertebrae, anus, trachea, esophagus,

renal) also has some association with UPJO (Kolton et al, 2000). Furthermore, VUR is seen in up to 40% of children with UPJO, albeit with a high degree of spontaneous resolution (Williams and Kenawi, 1976; Lebowitz and Blickman, 1983).

Indications for Surgery

Only approximately one third of affected children will need surgical intervention (Dhillon, 1998). The widely accepted indications for surgery are an increasing anteroposterior diameter on ultrasound, low or decreasing differential renal function, breakthrough infections while on prophylactic antibiotics, or symptoms such as pain in older infants and children. In infants, UPJO can be a cause of failure to thrive, feeding difficulties, and constipation.

However, most cases resolve with time and do not proceed to surgery. Hematuria is seen in some cases and is believed to result from disruption or rupture of mucosal vessels in the dilated pelvis (Kelalis et al, 1971; Williams and Kenawi, 1976). UPJO also has been shown to be a rare cause of hypertension most likely the result of renal functional deterioration and activation of the renin-angiotensin axis (Belman et al, 1968; Squitieri et al, 1974; Munoz et al, 1977; Grossman et al, 1981).

Surgical Repair

When indicated, surgical intervention can be performed by open surgery or laparoscopic and robot-assisted procedures. In infants, open access is the preferred procedure because the incision required

Figure 133-1. Intrinsic narrowing of upper ureter contributing to ureteropelvic junction obstruction.

Figure 133-2. A lower pole crossing vessel contributes to significant kinking at ureteropelvic and resultant intermittent obstruction. Often, when the ureter is mobilized, no evidence of intrinsic narrowing is found. However, dismembering and moving of the ureter anteriorly to the vessel prevents recurrence of the symptoms.

does not differ significantly from what is necessary for laparoscopic or robotic access. Debate is ongoing on whether minimally invasive procedures should be conducted through the transperitoneal or retroperitoneal routes even though the majority of pediatric urologists prefer retroperitoneal access when performing an open procedure. However, no proper randomized studies have yet been published comparing either the transabdominal or the retroperitoneal laparoscopic routes. The main argument for laparoscopic transperitoneal access is that the procedure is easier and familiar anatomic landmarks assist in orientation. However, ease should not stand alone as an argument for any kind of surgical access; other variables that need to factor in are potential risk for damage to intra-abdominal organs, postoperative urine leakage, and subsequent prolonged hospital stay, all of which tip the balance toward the retroperitoneal approach. Despite a longer learning curve and a more time-consuming procedure needed for retroperitoneoscopic pyeloplasty, we have preferred and advocated the use of retroperitoneoscopic pyeloplasty because the advantages seem to outweigh many of the potential difficulties encountered during the learning phase (Olsen and Jorgensen, 2004; Olsen, 2006; Olsen et al, 2007; Olsen and Rawashdeh, 2012).

Dismembered Pyeloplasty

Regardless of access, the Anderson-Hynes dismembered pyeloplasty technique is the preferred procedure for most surgeons and the gold standard against which all other interventions are compared (Anderson and Hynes, 1949). Originally developed for the repair of an obstruction in a retrocaval ureter, the procedure has since gained widespread acceptance as the standard UPJO repair, with a success rate of approximately 95% (Douville, 1953; Poulsen et al, 1987; O'Reilly, 1989; MacNeily et al, 1993; Shaul et al, 1994; Salem et al, 1995; McAleer and Kaplan, 1999; Austin et al, 2000; Casale et al, 2004; Bonnard et al, 2005). The initial concerns of compromising the blood supply and innervation of the proximal ureter have since been disclaimed (Douville, 1953). The advantage

of dismembering the UPJ is that a vessel crossing the lower pole can be preserved, the adynamic part of the ureter excised, and redundant pelvic tissue reduced (Fig. 133-4). In case of a long dysplastic segment of the upper ureter, complete mobilization of the kidney can bridge the distance between pelvis and ureter for several centimeters. In addition, a horizontal incision in the lower part of the pelvis can give further length and facilitate tension-free anastomosis (Fig. 133-5). Irrespective of access, the main steps of the Anderson-Hynes dismembered pyeloplasty are as follows (Fig. 133-6): after opening the Gerota fascia the anterior or posterior aspect of the UPJ is dissected (depending on the access used). The lower pole of the kidney is freed to avoid overlooking an accessory vessel, especially with the retroperitoneoscopic access. Electrocautery should be used with caution to minimize damage to the blood supply of both the pelvis and the ureter, with preference given to bipolar diathermy. A stay suture is placed in the pelvis proximal to the anticipated line of dismemberment; another stay suture can be placed in the ureter at the level of the stenosis. The UPJ is dismembered, and the pelvis reduced if indicated. A tensely dilated pelvis should be decompressed with a 21-gauge needle before dismembering, to avoid excessive pelvic reduction. The ureter is then spatulated along its lateral border, well beyond the dysplastic stenotic segment and carried through adequately into healthy ureteral tissue. At this stage, the stenotic part of the ureter should not be removed, because it can serve as a handle that minimizes ureteral tissue manipulation while performing the anastomosis, reducing the risk for mucosal edema. The anastomosis can be completed with interrupted or continuous suturing according to surgeon preference. Suture size depends on the prevailing anatomy, but most often a 6-0 or 5-0 resorbable monofilament suture on a round needle is used. Care should be taken at the tip of the V of the anastomosis, which has to be assembled precisely and in a tension-free manner. Placing inadvertent excessive tension on the stay sutures while aligning the anastomosis should be avoided because it can lead to kinking of the ureter once tension is relieved. Just before completing the anastomosis, the stenotic part of the

Figure 133-4. Anderson-Hynes dismembered pyeloplasty. A, Traction sutures are placed on the medial and lateral aspects of the dependent portion of the renal pelvis in preparation for dismembered pyeloplasty. A traction suture is also placed on the lateral aspect of the proximal ureter below the level of the obstruction. This suture will help maintain proper orientation for the subsequent repair. B, The ureteropelvic junction is excised. The proximal ureter is spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the ureter is then brought to the inferior border of the pelvis, and the medial side of the ureter is brought to the superior edge of the pelvis. C, The anastomosis is performed with fine interrupted or running absorbable sutures placed full thickness through the ureteral and renal pelvic walls in a watertight fashion.

Figure 133-5. A-C, The schematic represents a modified “bypass” pyeloplasty in which a side-to-side anastomosis of the ureter and renal pelvis is performed without transecting the stenotic ureteropelvic junction (UPJ). This allows the new UPJ to be configured within 1 cm of the lower pole parenchyma. It also keeps the ureter oriented by keeping it anchored to the pelvis during reconstruction, encouraging a “no touch” technique.

Figure 133-6. A, For a large or redundant pelvis, a reduction pyeloplasty is performed by excising the redundant portion between traction sutures. B, The cephalad aspect of the pelvis is then closed with running absorbable sutures down to the dependent portion. The dependent aspect of the pelvis is anastomosed to the proximal ureter as described in [Figure 133-4](#).

Figure 133-7. A, A Foley Y-V plasty is best applied to a ureteropelvic junction (UPJ) obstruction associated with a high insertion of the ureter. The flap is outlined with tissue marker or stay sutures. The base of the V is positioned on the dependent, medial aspect of the renal pelvis and the apex at the UPJ. The incision from the apex of the flap, which represents the stem of the Y, is then carried along the lateral aspect of the proximal ureter well into an area of normal caliber. B, The flap is developed with fine scissors. The apex of the pelvic flap is brought to the most inferior aspect of the ureterotomy incision. C, The posterior walls are approximated using interrupted or running fine absorbable sutures. D, The anastomosis is completed with approximation of the anterior walls of the pelvic flap and ureterotomy.

ureter is removed and the pelvis is irrigated with saline to avoid blood clots obstructing the ureter. Stenting the anastomosis and the nature of the stent used is a matter of choice that differs across surgeons and institutions. The kidney is brought back to its native position, and the anastomosis can be covered with perinephric fat if available. Usually the use of external drainage in the form of a Penrose is not indicated.

Nondismembered Pyeloplasty

Several techniques have been described for nondismembered pyeloplasty. Casale and colleagues (2004), in a comparative series of 26 children using the laparoscopic approach, showed that dismembered pyeloplasty gives results superior to those of nondismembered pyeloplasty of the Heineke-Mikulicz fashion. A feasible alternative is the Foley Y-V plasty, especially in cases with a high insertion of the ureter and no accessory vessels (Fig. 133-7). In a prospective randomized study, Szydelko and associates (2012), compared the outcome of Anderson-Hynes pyeloplasty and the Foley Y-V plasty with success rates of 95% and 86%, respectively, although the difference did not reach statistical significance. A vertical (Fig. 133-8) or spiral flap (Fig. 133-9) technique may be an option in cases of severe hydronephrosis with a long stenotic

ureteral segment, which makes tension-free primary anastomosis impossible. The bypass pyeloplasty (see Fig. 133-5) might be a feasible alternative although a systematic review of this technique is not available.

Surgical Approach to the Ureteropelvic Junction Obstruction

Posterior Lumbotomy

This approach should be reserved for infants and toddlers, because the increasing dorsal musculature with age can make this access difficult if not impossible (Fig. 133-10). In prone position, after a vertical incision has been made, the lumbodorsal fascia is incised and retracted laterally. The Gerota fascia is opened, giving direct access to the UPJ. The renal pelvis and the proximal ureter are then stabilized with stay sutures, and the UPJO repair is performed as previously described.

Flank Approach

In the supine position the affected side is supported by a gel roll. A small horizontal incision is made at the level of the tip of the 11th to 12th rib. The fascial and muscle layers are separated in a muscle-splitting fashion. Currently, and because pyeloplasties in older children are mostly performed laparoscopically, division of the muscle fibers is deemed unnecessary. The peritoneum is liberally loosened from the abdominal wall muscles and swept medially, thus giving access to the Gerota fascia. The fascia is opened vertically and pushed medially. The UPJ is dissected and stabilized with stay sutures in the pelvis and proximal ureter. The pyeloplasty is then performed as described previously.

Minimally Invasive Techniques

Endoscopic Approach

The antegrade and retrograde endoscopic approach to the UPJO was popularized in the late 1980s and 1990s with varying results. The reported success rate on long-term follow-up of balloon dilatation in patients younger than 18 years of age was 25% (Osther et al, 1998), and the ureteral cutting balloon catheter showed a success rate of 78% in adults (Kim et al, 1998), including two patients requiring embolization of a lower pole vessel because of gross postoperative hematuria. They recently reported a review of their 25 years of experience with endopyelotomy and found a success rate of 62% in primary UPJO, whereas the success rate in secondary UPJOs resulting, for example, from scarring was as high as 94% (Kim et al, 2012). Antegrade pyelotomy should be reserved for older children and adolescents with moderate hydronephrosis (Figenshau and Clayman, 1998). However, preoperative screening for accessory vessels is required by computed tomography (CT), magnetic resonance imaging (MRI), or transluminal ultrasound, so as to avoid vascular injury. Additionally, fluoroscopy is needed during the procedure, which leads to significant radiation exposure and makes this approach less attractive in pediatrics. However, endopyelotomy may have a place in the management of failed primary open or laparoscopic procedures (Fig. 133-11), followed by the placement of a double-pigtail catheter for 6 weeks. In these cases, the precise anatomy is known from the primary procedure in which absence of an accessory vessel is documented. However, patients should be carefully selected and a repeat pyeloplasty, either open or laparoscopically, is the best choice in most cases.

Laparoscopic Pyeloplasty

The first cases of laparoscopic pyeloplasty were reported in 1993 (Kavoussi and Peters, 1993; Schuessler et al, 1993). Tan and Roberts (1996) reported the first preliminary results of the transabdominal approach, and Yeung and colleagues (Yeung et al, 2001) described

Figure 133-8. A, Vertical flap technique may be used when a dependent ureteropelvic junction (UPJ) is situated at the medial margin of a large, box-shaped extrarenal pelvis. In contrast to the spiral flap, the base of the vertical flap is situated more horizontally on the dependent aspect of the renal pelvis, between the UPJ and the renal parenchyma. The flap itself is formed by two straight incisions converging from the base vertically up to the apex on either the anterior or posterior aspects of the renal pelvis. As for the spiral flap, the position of the apex determines the length of the flap, which should be a function of the length of proximal ureter to be bridged. The medial incision of the flap is carried down the proximal ureter completely through the strictured area into normal-caliber ureter. B, The apex of the flap is rotated down to the most inferior aspect of the ureterotomy. C, The flap is closed by approximating the edges with interrupted or running fine absorbable sutures.

the retroperitoneal approach in infants and children. The evolution of both instruments and video equipment has made the laparoscopic approach widely accepted, and it has become the method of choice at many centers (Bonnard et al, 2005; Metzelder et al, 2006; Sweeney et al, 2011; Blanc et al, 2013).

Transperitoneal or Retroperitoneal Approach. From a theoretical point of view, the retroperitoneal approach should be safer and is the route of choice in open surgery. However, only few studies have compared retroperitoneal with transperitoneal access and without noting any significant differences in the outcome and/or complications. Abuanz and associates (2010) found a higher rate of conversion to open surgery in adults when using the retroperitoneal approach compared to the transabdominal route. This might reflect a more technically challenging procedure in the retroperitoneum. Canon and colleagues (2007) reported a longer operative time for the retroperitoneal approach. Larger randomized studies have not been published so far.

Robot-Assisted Pyeloplasty. In the beginning of this century, the first publications on robotic pyeloplasty in children emerged (Olsen and Jorgensen 2004; Kutikov et al, 2006; Lee et al, 2006). The transperitoneal approach has gained wide acceptance, whereas the retroperitoneal approach seems to have attracted fewer proponents, undoubtedly because of a more technically challenging procedure in children with the confined working space, difficult orientation, and relatively large instruments that need to be maneuvered (Olsen et al, 2007). Robotic-assisted pyeloplasty has a shorter and more efficient learning curve compared to that of laparoscopy because of advanced visualization through three-dimensional vision and the dexterity of the instruments provides for easier manipulation, precise dissection, and suturing. Recently Barbosa and associates (2013) compared open and robot-assisted pyeloplasty in a larger series and found comparable outcomes but a faster resolution rate in the robotic group. Others (Lee et al, 2006; Dangle et al, 2013) found similar results. Peters (2011) describes the robot-assisted transperitoneal technique, and Olsen

and Rawashdeh (2012) describe the robot-assisted retroperitoneal technique in detail.

Technique of Laparoscopic or Robotic-Assisted Pyeloplasty. With the patient in a 45- to 60-degree flank position, port placement of the transperitoneal approach is shown in Figure 133-12. The caudal port can be placed more medially in cases of large hydronephrosis or in small children. The primary access for the camera port is established using the open technique, and instrument ports are placed under visual guidance. On both sides, retrocolic access is feasible. However, most surgeons prefer a transmesenteric approach on the left side (Lee et al, 2006; Gupta et al, 2009; Sedlacek et al, 2010; Khan et al, 2011; Shadpour et al, 2012) because of the shorter operating time, lower morbidity, reduced hospital stay, and no difference in outcome compared to the retrocolic approach. If the pelvis cannot be identified through the mesocolon, the ureter should be identified and followed to the UPJ with attention paid to the possible presence of any accessory vessel (Peters, 2011). The UPJO can then be stabilized by a stay suture, and surgery is performed as detailed earlier. Essentially, there is no difference in port placement between a laparoscopic transabdominal or robot-assisted approach.

For the retroperitoneal approach, port placement varies in accordance with the use of laparoscopic or robotic instruments (Fig. 133-13). In both cases, the patient is placed in an 80- to 90-degree flank position. A small gel roll is placed under the contralateral iliac crest, and the upper leg is stretched (Fig. 133-14). The table should not be flexed, because this will diminish the anteroposterior diameter of the retroperitoneal space. During the retroperitoneoscopic procedure with standard instruments, the surgeon is placed behind the patient (dorsally) (see Fig. 133-13A) (Bonnard, 2005), providing better ergonomics. Small children might even be placed diagonally on the table, exposing the instruments in a right angle to the surgeon. In the robot-assisted procedure, the robot is docked from a cranial position and, contrary to the case in laparoscopy, camera position is relatively fixed and

Figure 133-9. A, Spiral flap may be indicated for relatively long areas of proximal ureteral obstruction when the ureteropelvic junction (UPJ) is already in a dependent position. The spiral flap is outlined with the base situated obliquely on the dependent aspect of the renal pelvis. The base of the flap is positioned anatomically lateral to the UPJ between the ureteral insertion and the renal parenchyma. The flap is spiraled posteriorly to anteriorly or vice versa. The anatomically medial line of incision is carried down completely through the obstructed proximal ureteral segment into normal-caliber ureter. The site of the apex for the flap is determined by the length of the flap required to bridge the obstruction. The longer the segment of proximal ureteral obstruction, the farther away is the apex, because this will make the flap longer. To preserve vascular integrity to the flap, however, the ratio of flap length to width should not exceed 3:1. B, Once the flap is developed, the apex is rotated down to the most inferior aspect of the ureterotomy. C, The anastomosis is completed, usually over an internal stent, using fine absorbable sutures.

cannot easily be changed during the procedure. In both cases a muscle-splitting dissection is carried out at the camera port site and the lumbodorsal fascia is opened. The retroperitoneal space is then developed into a 200- to 300-mL working space, depending on the size of the patient. This is done with either a homemade balloon using a 12-Fr catheter with the finger of a latex surgical glove secured to its tip or a commercially available balloon. The latter can be difficult to use in small children because of the large size of these dilators. Additional ports are placed under digital or visual guidance. Use of an extra 5-mm assistance port in the iliac fossa is recommended to facilitate suture delivery and suction during the procedure, because removing and replacing robotic instruments for that same purpose is much more cumbersome and time-consuming. After opening the Gerota fascia the UPJ and the pelvis are dissected. A stay suture in the pelvis brought intracorporeally through the abdominal wall provides needed tension and alignment. The pyeloplasty is then performed as described earlier. In case of a UPJO in a horseshoe kidney, the retroperitoneal approach is not advisable because the pelvis is approached from behind. This advice applies for the retroperitoneal approach in the rare case of a retrocaval ureter, at least for the robot-assisted procedure. Even with standard laparoscopic equipment, retroperitoneal access in these cases is difficult. On the other hand, retroperitoneal access to a UPJO of a lower moiety in a duplex system with the subsequent challenging repair is a perfect case for the robot (see Fig. 133-3).

Stones and Congenital Hydronephrosis. Occasionally, pelvic/renal stones are found with congenital hydronephrosis. Regardless of whether open or laparoscopic/robotic access is used, the treatment of choice is with a flexible cystoscope. In minimally invasive surgery the cystoscope can be brought in through either a laparoscopic or a robotic port. Alternatively a flexible ureteroscope can be used. However, the latter makes stone removal more cumbersome. Standard techniques for stone removal are used as described elsewhere in this text.

Vascular Hitch. Originally described by Hellström and associates (Autorino et al, 2014), the vascular hitch technique (Fig. 133-15) has regained acceptance among laparoscopic surgeons, probably because it is easier to perform than pyeloplasty (Sakoda et al, 2011). However, the technique is feasible only in cases of an anterior lower pole vessel without any intrinsic obstruction of the UPJ. Gundeti and colleagues (2008) conclude that the vascular hitch should be reserved for cases with “moderate hydronephrosis with no calyceal dilatation and a well-preserved cortex, poor renal drainage with preserved split function and lower pole crossing vessels. Intraoperative criteria included a normal ureter and ureteropelvic junction with peristalsis.” Long-term results are lacking (Gundeti et al, 2008; Schneider et al, 2013), and one can speculate whether this technique of embedding the vessel in the pelvic tissue can lead to hypertension later in life.

Stenting. Most surgeons prefer stenting the UPJ, both in open and minimally invasive surgery (Austin et al, 2000). This decreases the

risk for leakage from the anastomosis and subsequent urinoma formation or, if the transperitoneal route is chosen, bowel paralysis resulting from urinary ascites. Stentless anastomoses have been advocated by some authors (Liss et al, 2013). This mandates extra careful tissue handling to avoid edema and subsequent obstruction

Figure 133-10. Positioning of patient for left posterior lumbotomy incision. An oblique incision is made from the angle of the 12th rib down to the iliac crest at a point one third the distance from the anterior superior iliac spine to the spinal processes.

and leakage from the reconstructed UPJ in the postoperative period. Stenting with double-pigtail catheters in children consigns the patient to another anesthesia for stent removal and adds significant time to the procedure when done in connection with the pyeloplasty. Use of a stent with an extraction string and placed retrograde can be a feasible alternative. Antegrade preoperative stenting with double-pigtail catheters also can pose difficulties in passing the ureterovesical junction, which can be quite narrow in small infants. For purposes of confirming stent position in the bladder, instillation of methylene blue into the bladder has been advocated. Retrograde stenting immediately before the procedure might make the anastomosis more difficult, and if done days to weeks before surgery as in cases in which emergent diversion is necessary because of obstruction, anastomosis might be more challenging as a result of local tissue inflammation caused by the catheter traversing the UPJ. It is our experience to divert with a nephrostomy tube in the rare patient with hydronephrosis who needs emergent diversion in close temporal proximity to definitive surgery, because the inflammation caused by a nephrostomy is less severe at the UPJ.

We prefer using a transanastomotic ureteropyelostomy tube, the so-called BLUE stent (Helmy et al, 2011), brought out through the renal parenchyma through a middle calyx or directly through the upper part of the anastomosis and the lateral abdominal wall (Fig. 133-16). This externalized stent is kept open for 24 to 48 hours, after which it is knotted and kept in situ for 7 to 14 days and simply pulled out without the need for anesthesia. In cases of obstruction, infection, or postoperative pain, the knot is released and the transanastomotic ureteropyelostomy drains the system acting as a nephrostomy tube.

It is customary to leave the bladder drained by Foley catheter for up to 24 to 48 hours postoperatively. Although dogmatic and not based on hard evidence, it makes perfect sense when the anastomosis is stented by a double-pigtail catheter because VUR will be present, transferring bladder pressure unhindered to the

Figure 133-11. A, Right antegrade nephrostogram performed 2 months after dismembered pyeloplasty, demonstrating persistent obstruction at the ureteropelvic junction (UPJ). A nephrostomy tube was placed 2 weeks after surgery, after the patient developed flank pain, fever, and *Staphylococcus aureus* urinary tract infection. B, Acuise balloon being inflated across the UPJ narrowing. Note waist present in balloon (upper arrow) and cutting wire positioned laterally (lower arrow).

renal pelvis. However, it is unnecessary when using an externalized transanastomotic ureteropyelostomy tube because the lower end of the stent is removed before placement and does not traverse the ureterovesical junction.

Surgical Outcome and Complications

In general, pyeloplasty is a safe procedure with few complications and a high success rate between 90% and 100% (Poulsen et al, 1987; O'Reilly, 1989; MacNeily et al, 1993; Shaul et al, 1994; Salem et al, 1995; McAleer and Kaplan, 1999; Austin et al, 2000; Houben et al, 2000; Casale et al, 2004; Bonnard et al, 2005; Peters, 2011; Olsen and Rawashdeh, 2012; Autorino et al, 2014). However, the definition of *success* is wide ranging and covers everything from cessation of symptoms to improvement or at least stability of function of the affected kidney to decreasing anteroposterior diameter of the hydronephrosis on ultrasound, and more rigidly *failure* as the need for reoperation or reintervention. This

makes the comparison among different outcome studies difficult if not impossible.

Perioperative complications include bleeding from ureteral or pelvic vessels, which can be handled preferably by bipolar diathermy in most cases. Bleeding is the most commonly reported reason for conversion in minimally invasive procedures, followed by lack of progression or difficulties dissecting the UPJ. Postoperatively, infection, pain, and increasing dilatation might be early signs of a failed reconstruction (Lindgren et al, 2012). However, blood clots and edema may be the cause and usually will resolve within a few days, but may require temporary diversion by nephrostomy tube. In the long term, decreasing kidney function and increasing dilatation may indicate the need for further intervention, initially by balloon dilatation/incision of the stenotic UPJ (see Fig. 133-11) and stenting for 4 to 6 weeks, but may ultimately require a repeat pyeloplasty. In such cases, retroperitoneal access can be cumbersome because of scarring and a transperitoneal approach is preferred. If scarring of the ureter is severe and mobilization of the kidney and ureter does not allow for an appropriate length to perform a tension-free anastomosis, a ureterocalicostomy should be considered. This can be done openly or with laparoscopic or robotic-assisted procedures (Fig. 133-17).

Figure 133-12. Port placement in transabdominal laparoscopic or robotic-assisted pyeloplasty.

MEGAURETER

Definition

The term *megaureter* is a descriptive one denoting dilatation of the ureter irrespective of cause. Originally coined by Caulk in 1923 as megaloureter, other synonyms in use include wide ureter and hydroureter and in general refer to a ureter that has a diameter of 7 mm or greater based on the studies of Cussen (1967) and Hellström (1985), which defined the upper limit of the range of normal ureteral diameters in children up to 16 years of age as being 0.50 to 0.65 mm. The cause of megaureters is either primary, representing a condition intrinsic to the ureter itself, or secondary to bladder pathologic processes, such as neurogenic bladder dysfunction, bladder outlet obstruction, and/or infection. Megaureters have been subclassified into four categories based on causality; obstructed, refluxing, nonobstructed nonrefluxing, and refluxing with obstruction (Smith 1977; King 1980). In circumventing the refluxing type, which is easily diagnosed and is dealt with elsewhere in this book, distinguishing between obstructed megaureters and those that are nonobstructed, nonrefluxing can be challenging. For, as is the case with hydronephrosis, the mere presence of ureteral

Figure 133-13. Port placement in retroperitoneal approach. A, Approach with standard laparoscopic instruments. B, Approach with robotic-assisted instruments.

KEY POINTS: PYELOPLASTY

- UPJO typically is due to either an intrinsic narrowing in which the ureteral segment has an interruption in the development of the circular musculature of the UPJ, an alteration in collagen fibers in and around the muscular cells, or an extrinsic obstruction that is seen in association with aberrant, accessory, or early branching lower pole vessel that passes anteriorly to the UPJ or proximal ureter and contributes to mechanical obstruction.
- Congenital renal malformations can be commonly seen in association with a UPJ, with a contralateral UPJO being the most common anomaly, followed by renal dysplasia and multicystic dysplastic kidneys.
- The surgical approach favored in the repair of a UPJO obstruction is the dismembered pyeloplasty, which has been shown to be effective because of its broad applicability, means of allowing excision of the pathologic segment in question, and facilitation of a reduction pyeloplasty when necessary.
- Laparoscopic pyeloplasties provide excellent visualization of the anatomy, enhance cosmesis, and duplicate the results of open pyeloplasties with short-term follow-up. The technical challenges of this approach have been facilitated by the use of a robotic-assisted procedure that improves the anastomotic repair.
- Complications from a pyeloplasty include prolonged urinary drainage postoperatively, lack of improvement in renal function or improvement in washout, and, occasionally, worsening hydronephrosis and diminished renal function postoperatively. Such a situation may lend itself to a repair using endoscopic procedures or a repeat dismembered pyeloplasty.

dilatation, which at times can be quite alarming on imaging, does not necessarily indicate significant obstruction. **The challenge is in the balance between early identification and management of the obstructed ureters, to prevent renal functional deterioration, and that of not consigning ureters with balanced stable dilatations to unnecessary intervention.**

Cause, Occurrence, and Presentation

The pathophysiology of primary obstructed megaureters (POM) has not been fully ascertained, but there is general agreement that obstruction results from the presence of an abnormal adynamic segment at the terminal end of the ureter near or at the ureterovesical junction (UVJ). Insufficient peristalsis at the UVJ leads to obstruction and upstream dilatation. Fetal animal studies by [Tanagho \(1973\)](#) and [Pirker and associates \(2007\)](#) demonstrated that the ureteral muscular layers develop in a craniocaudal direction, leaving the juxtavesicular part of the ureter to develop last, with maturation of this terminal part continuing postnatally. This corresponds well with studies in human fetuses that showed a

Figure 133-15. A and B, Vascular hitch in cases with crossing vessels and without intrinsic obstruction of the ureteropelvic junction (UPJ). After the removal of all adhesences between the UPJ and the vessel, the latter is moved cranially on the pelvis and then embedded into pelvic tissue with nonresorbable sutures.

Figure 133-14. Patient positioning for the retroperitoneoscopic examination. The contralateral iliac crest is supported by a gel roll. The table is not flexed, to avoid a reduction of the anteroposterior diameter in the retroperitoneal space. The upper leg is stretched, and the lower leg is bent. This positioning is not advisable for adult patients.

Figure 133-16. Transanastomotic ureteropyelostomy BLUE Stent. The lower coil is removed, and the upper end is brought out to the skin, through either the anastomosis or the renal parenchyma. The stent is left open for 24 to 48 hours and then knotted. It can easily be removed after 7 to 14 days without the need for anesthesia.

Figure 133-17. Ureterocalicostomy. A, The ureter is identified in the retroperitoneum and dissected proximally as far as possible. The kidney is mobilized as much as necessary to gain access to the lower pole and subsequently perform the anastomosis without tension. A lower pole nephrectomy is performed, removing as much parenchyma as necessary to widely expose a dilated lower pole calyx. B, The proximal ureter is spatulated laterally. The anastomosis subsequently should be performed over an internal stent and consideration given to leaving a nephrostomy tube. The initial suture is placed at the apex of the ureteral spatulation and the lateral wall of the calyx, with another suture placed 180 degrees from that. C, The anastomosis is completed in an open fashion, placing each suture circumferentially but not securing them until the anastomosis has been completed. D, The renal capsule is closed over the cut surface of the parenchyma whenever possible. However, the capsule should not be closed close to the anastomosis itself because that may compromise the lumen by extrinsic compression. Instead, the anastomosis should be protected with a graft of perinephric fat or with a peritoneal or an omental flap.

similar directional maturation with typical fetal circular muscular fibers first maturing to the double muscle layer of the full-term infant well past delivery, a fact that may explain transient dysfunctions at the UVJ and the spontaneous resolution of some POMs with age (Matsuno et al, 1984; McLellan et al, 2002). Other studies point to the presence of excessive and abnormal collagen deposition at the narrow part of the ureter (Notley, 1968; Gosling and Dixon, 1978) or presence of a thick enveloping sleeve of muscle surrounding the muscle bundles of the terminal ureter (Dixon et al, 1998). Most recently Kang and colleagues (2009) demonstrated abnormalities in the interstitial cells of Cajal in POM, cells whose primary function is related to smooth muscle contractility, pacemaker activity, and ultimately peristalsis.

The true incidence of POM is not known but is thought to average 10% to 23% of antenatally detected upper urinary tract dilatations (Brown et al, 1987; Gokce et al, 2012). The anomaly has a predilection for boys and the left side. It is bilateral in 25% of cases and is associated with contralateral dysplasia or obstruction in 10% to 15% of cases (Joseph, 2007). Most POMs are detected by antenatal ultrasound screening, with the vast majority being asymptomatic. Brown and colleagues (1987) clearly demonstrated the impact of prenatal ultrasound in that the majority (79 %) of patients with POM—constituting 23% of antenatally detected dilatations—were detected antenatally as opposed to the era before ultrasound, when only 8% of patients presenting symptomatically and consequently found to have upper urinary tract dilatation were diagnosed with POM (Brown et al, 1987). When present, symptoms include those of UTI, abdominal pain, and microscopic hematuria, even in the absence of infection. This is believed to result from the disruption of urothelial microvasculature because of distention or calculi. In rare instances, previously undiagnosed patients can

present with an abdominal mass, although this is more a feature of the era before the ultrasound era, as is the current very infrequent manifestation with signs and symptoms of renal impairment (Shokeir and Nijman, 2000).

Surgical Indications

By historical account it can be deduced that the majority of non-refluxing megaureters run a benign course and resolve spontaneously within the first few years of life (Matsuno et al, 1984; Brown et al, 1987; McLellan et al, 2002; Shukla et al, 2005). This has been confirmed in a prospective observational study by Ranawaka and Hennayake (2013), who were able to show that complete resolution and time to resolution were inversely related to ureteral diameter with minimal complications or febrile episodes during follow-up for those with a ureteral diameter less than 10 mm while maintained on antibiotic prophylaxis and virtually none proceeded to surgery. On the other hand, patients with ureteral diameters greater than 10 mm were more prone to complications such as recurring febrile UTIs, stone formation, and abdominal pain, with only 17% resolving completely and an overall 21% requiring surgical intervention. Persistence of dilatation therefore warrants continued close follow-up of these patients with periodic ultrasound examinations supplanted with functional studies when deemed necessary until resolution or stability of dilatation is confirmed. The role of extended follow-up into early adulthood also has been advocated based on worsening of some previously stable megaureters at or beyond puberty (Shukla et al, 2005).

Therefore a steady trend toward nonoperative management of patients with megaureters has occurred during the last 25 years. An increased understanding of the pathophysiology of this condition

combined with advances in minimally invasive procedures also has shifted management in a more minimally invasive direction. Surgery in the case of POM is to be considered when patients are symptomatic or have recurring UTIs, progressive unremitting dilatation on ultrasound, differential renal function less than 40%, and/or significant decreases in differential renal function of 5% or greater on sequential “comparable” renal nuclear functional studies (Farrugia et al, 2014). Several studies cite prolonged washout or drainage curves on diuretic renograms as being an indication to intervene, because prolongation of half-life is equated with significant obstruction. However, relying on renographic washout curves as a measure of obstruction is problematic and can be misleading, because it has been shown that washout curves in neonates and infants can be affected by many factors other than restriction of flow: renal function and the ability to respond to diuretic stimulation, hydration status, posture, distensibility, and volume of the collecting system, in addition to matters related to procedural and technical aspects, such as the timing of diuretic administration and curve interpretation. Collectively, these variables limit the usefulness of drainage curves, as has been documented in a study that reported false-positive results in up to 44% of renographies (O'Reilly, 1989; Shokeir and Nijman, 2000; Amarante et al, 2003).

Surgical Management

Basic principles of megaureter correction are simple and straightforward; the surgical procedure can be quite demanding, however, and should be reserved for the pediatric urologist with experience in bladder and ureteral surgery and in whose hands good results

can be achieved. In summary, the stenotic distal part of the ureter is excised, the megaureter is straightened, then tapered to facilitate reimplantation in a nonrefluxing fashion with adequate length-to-diameter ratio of 5:1 so as to improve coaptation of the ureteral lumen whereby effective peristalsis and urine transportation are achieved (Paquin, 1959). Several eponymous procedures have been described for ureteral remodeling and its reimplantation, and with time numerous modifications and refinements have emerged. As the laparoscopic and robotic envelopes continue to be pushed, the same basic principles are increasingly being achieved by laparoscopic and robot-assisted techniques, albeit at a limited number of centers.

If prompt decompression of a POM is necessary, this can be achieved by nephrostomy tube diversion; however, nephrostomy tubes are difficult to maintain in infants for prolonged periods and carry the risk for leakage, infection, and displacement. A better temporizing option in this case would be distal cutaneous ureterostomy. This simple technique allows rapid decompression of the dilated and potentially infected system and allows a delay in definitive reconstruction, which is usually warranted in infants in whom incongruity between the small bladder and the severely dilated ureter does not allow for a safe nonrefluxing reimplantation and the general reluctance to perform reimplantations in infants for fear of inducing bladder dysfunction, a claim that may be overstated according to a study by de Kort and colleagues (2002). The ureter can be approached through a small oblique inguinal incision, carried through muscle-splitting dissection to the perivesical space (Fig. 133-18). The dilated tortuous ureter is identified and picked up by nontraumatic forceps or a noncrushing Allis clamp. Peritoneal adhesions may have to be swept off using a

Figure 133-18. Diversion with ureterostomy. A, A small oblique or transverse inguinal incision is made. B, Muscles are separated bluntly, and the perivesical space is accessed. The dilated tortuous ureter is identified, the obliterated umbilical artery being divided and ligated if necessary. C, The ureter is mobilized and brought out as a loop to the incision, where it is fixed to the fascia, and the incision is approximated to the ureteral wall. D, The ureter is now opened, and the edges are everted and fixed to the skin with fine resorbable monofilament interrupted sutures.

pledget. A vascular loop is pulled under the ureter to allow atraumatic handling. The ureter can now be pulled out into the incision as a loop and secured to the fascia with several resorbable monofilament 5-0 sutures, whereafter the fascia is approximated to the distended ureter with the same suture. The ureter can now be opened transversely and the edges everted and secured to the skin using 5-0 or 6-0 resorbable monofilament sutures. A drainage catheter can be left in situ for the first 24 to 48 hours to aid in drainage and decompression of the redundant dilated system. Because of the dimensions of the ureter, stenosis of the stoma is a rare occurrence (Rabinowitz et al, 1977; Kitchens et al, 2007). Another temporizing procedure that is gaining acceptance in the infant is that of internal diversion by means of a refluxing reimplantation. The dilated ureter is transected proximal to the stenotic terminal part and is anastomosed directly in a freely high-grade refluxing fashion

whereby “dangerous” obstruction is converted into the “lesser evil” of VUR. Preliminary studies have shown promising results of this temporizing procedure; however, long-term outcomes with regard to effect of reflux on renal function are awaited (Lee et al, 2005; Farrugia et al, 2014; Kaefer et al, 2014).

Definitive reconstruction entails remodeling and reimplanting the ureter in a nonrefluxing fashion. The bladder is accessed through a low transverse Pfannenstiel incision; in redo cases a vertical lower abdominal incision might be preferable because it allows more extensive cranial mobilization of the ureters (Fig. 133-19). The bladder is opened in the midline between stay sutures, and the index ureteral orifice is identified and cannulated with a baby feeding tube of appropriate size—usually 5 or 6 Fr—and secured to the mucosa with a 5-0 monofilament resorbable suture. This aids in the dissection of the ureter and provides an invaluable handle

Figure 133-19. Remodeling and reimplantation of primary obstructed megaureter. A, A 5-Fr feeding tube typically passes up a normal-caliber intravesical segment of primary obstructive megaureter. B, After the megaureter is freed from its intravesical and extravesical attachments, a blunt right-angle clamp is used to clear the peritoneum from the posterior and base of the bladder. If extravesical dissection is necessary, it is advisable to make the new hiatus before moving outside the bladder. A right-angle clamp is incised upon and spread. C, A vascular loop marks the new hiatus by being pulled from within the bladder to the outside and then through the old hiatus. D, A right-angle clamp is guided from within the bladder to the perivesical space, where it is identified and incised upon. The ureter is brought extravesically by grasping the traction suture in the ureter.

for traction. The dilated ureter can now be mobilized into the bladder by dividing its intravesicular and extravesicular attachments. Care must be taken to preserve the blood supply to the distal ureter, which usually emanates medially. Once the ureter is mobilized within the bladder, the technique of reimplantation and remodeling must be decided on, because they dictate the next steps. In the case of an intravesicular repeat implant, such as the Cohen transtrigonal or the Politano-Leadbetter, work can be continued from within the bladder. However, it is advisable to move outside the bladder in cases of a very large ureter or to perform the whole dissection, transection, and remodeling of the ureter extravesically and proceed with an extravesicular form of reimplantation especially if the discrepancy between ureteral diameter and bladder is significant, so as to avoid excessive bladder dissection and creation of a very large hiatus in the trigone area (Perovic, 1994). Should the Politano-Leadbetter procedure be chosen (see Fig. 133-19), an appropriate site for the new hiatus superiomedially is identified and a blunt right-angled clamp is carefully passed

through the original hiatus, which may need to be widened, and the clamp is probed toward the new planned hiatus while taking care to sweep off the peritoneal attachments from the posterior aspect of the bladder. Once the clamp is in position and palpable digitally from inside the bladder, the clamp's right angle is pushed inward, opened slightly, and the jaws of the right angle clamp are incised upon the branches, thereby creating the new hiatus, which then can be widened appropriately. A vascular loop is passed from within the bladder from the new to the old hiatus, thereby traversing extravesically. The dilated ureter is now guided out of the bladder, allowing further mobilization and release. After remodeling (Fig. 133-20), the ureter is brought back into the bladder through the new hiatus guided by the vascular loop. The original hiatus is closed with a 4-0 monofilament resorbable suture, and a new submucosal tunnel is created toward the new hiatus. The ureter is now pulled through and shortened adequately to the length of the tunnel; the ureteral orifice is hitched to the detrusor with a 5-0 monofilament resorbable suture at the 6 o'clock position, and the

Figure 133-20. Remodeling and reimplantation of primary obstructed megaureter completed. **A,** The tailored ureter is brought back into the bladder through the new hiatus. **B,** After closing the original hiatus, a new submucosal tunnel is made to the new hiatus. **C,** The distal portion of ureter is resected to match the length of the tunnel. **D,** The revised ureter is anastomosed to the bladder with fine interrupted sutures.

mucosa is adapted circumferentially to the bladder mucosa in the new position with 6-0 interrupted monofilament resorbable sutures. Postoperatively the bladder is decompressed with a Foley catheter for a few days.

Tailoring of the ureter can be achieved by one of two basic ways: plication or excisional tapering. With plication the mega-ureter is imbricated or folded around an 8- or 10-Fr catheter, depending on patient age. Ureteral redundancy is marked by brief placement of atraumatic Allis clamps around the ureter containing the medialized catheter. After removing the clamps the Starr plication technique (Fig. 133-21) dictates imbricating the redundant lateral edge of the dilated ureter by multiple interrupted 5-0 monofilament resorbable sutures in the Lembert fashion along the clamp impressions (Starr, 1979). Whereas in the Kalicinski plication

Figure 133-21. Starr plication. Ureteral plication is performed over the appropriate catheter, with interrupted 5-0 monofilament resorbable sutures placed in Lembert fashion (after Starr). (From Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, editor. Difficult problems in urologic surgery. Chicago: Year Book Medical; 1989. p. 131.)

Figure 133-22. Kalicinski folding technique. Ureteral folding technique. A running suture is longitudinally woven through the mega-ureter to create two lumens. This isolates the best-vascularized portion as a functional ureter (catheter within) and excludes redundancy. The redundant portion is then folded, and the two are tacked together with interrupted sutures. (From Kalicinski ZH, Kansy J, Kotarbinska B, et al. Surgery of megaureters: modification of Hendren's operation. J Pediatr Surg 1977;12:183.)

(Fig. 133-22) a 6-0 monofilament resorbable suture is woven in a continuous fashion craniocaudally through the ureteral wall along the clamp impressions, thereby defunctionalizing the redundant lateral aspect, which in turn is folded back and fixed along the catheterized lumen with multiple 6-0 interrupted sutures (Kalicinski et al, 1977). In plication techniques the blood supply to the ureter is preserved as the ureteral walls are kept intact, thereby decreasing the risk for ischemia and stenosis (Bakker et al, 1988). Folding techniques, however, are suitable only for the moderately dilated ureter (<1.75 cm in diameter) (Fretz et al, 2004) because a diameter that is too large will result in a bulky remodeled ureter that is difficult to reimplant and significantly increases complications and failure rates (Parrott et al, 1990). In general, good results have been reported with folding techniques, with success rates of 90% to 95% (Ehrlich 1985; Perdzynski and Kalicinski, 1996; Daher et al, 1999; Fretz et al, 2004). Postoperatively stents in the form of baby feeding tubes or double-pigtail catheters are left in situ for 7 days and 4 weeks, respectively, for drainage purposes. Follow-up pyelography via stentograms is not indicated at stent removal.

Excisional tapering as originally described by Hendren (1969) was the forerunner for the later modifications of folding techniques, because it is thought and has been shown that excisional tapering may jeopardize ureteral vasculature with all its attendant complications (Bakker et al, 1988; Whitmore and Ehrlich 1988; Parrott et al, 1990). Nonetheless, the Hendren procedure has advantages, especially when dealing with massively dilated ureters that are not amenable to folding, and when performed with care the risk for vascular compromise should be minimal.

The procedure (Fig. 133-23) follows the same principal steps of defining the redundant less vascular lateral part of the ureter around an 8- to 10-Fr catheter. Instead of folding, the excess ureteral tissue is excised and closed with a running locking 6-0 resorbable monofilament suture along the proximal two thirds of the ureteral length to be remodeled; the distal third is closed by interrupted sutures of the same kind to allow for appropriate shortening of the ureter at reimplantation without violating the integrity of the running anastomosis (Hendren, 1969). The same postoperative regimen is followed as with the folding techniques. Although success rates with this method have generally been excellent,

Figure 133-23. Excisional tapering. Tapering is done over an 8-Fr red rubber catheter in infants or a 10-Fr catheter in older children and adults. After vascularity is defined, special atraumatic clamps are placed over the catheter. Baby Allis clamps help retract the portion of ureter to be resected, which is usually lateral. It is important not to resect too much ureter. Running 5-0 monofilament resorbable suture is used to reapproximate the proximal two thirds of the ureter. Its distal third is closed with interrupted sutures to allow for shortening.

exceeding 90% in many studies (Hendren, 1969; Parrott et al, 1990; DeFoor et al, 2004), refinements aimed at preserving vasculature by limiting excision to the mucosal and muscular parts of the redundant ureter, and leaving behind the vascular rich adventitial layers may even improve on these outcomes by lowering the risk for ischemia (Ossandon et al, 2005). It is pertinent for all types of ureteral remodeling that tapering be gradual so as not to cause an abrupt change in ureteral caliber, which may cause a form of obstruction.

Laparoscopic ureteral remodeling and reimplantation follows the same general principles set for open techniques. An increasing number of reports are demonstrating the feasibility and success of these minimally invasive techniques with excellent short- to medium-term outcomes fully comparable with those of open procedures (Bi and Sun, 2012; Abraham et al, 2012; Bondarenko, 2013). Extravesicular reimplantations seem to dominate because technical limitations impede tapering from within the bladder (Abraham et al, 2012; Bondarenko, 2013) notwithstanding that a recent report has shown pneumovesicular laparoscopic excisional tapering and transtrigonal reimplantation achievable (Bi and Sun, 2012). Robot-assisted reimplantations for VUR in children are well established but have yet to develop for POM (Marchini et al, 2011; Smith et al, 2011).

Outcomes

In general, techniques of ureteral remodeling and reimplantation for POM have stood the test of time, producing excellent and durable results of over 90% success rates in several studies. Interestingly, outcomes for patients with POM have generally been better than those for patients with refluxing megaureters, a fact that may be explained by histologic changes in the ratios of collagen to smooth muscle in the UVJ of refluxing ureters, which may result in a stiffer, less compressible ureter (Lee et al, 1998; DeFoor et al, 2004). Worse outcomes also have been reported in patients with dysfunctional voiding, neurogenic bladders, and other concomitant lower urinary tract pathologic conditions such as posterior urethral valves and obstructed flow (DeFoor et al, 2004; Carr and Casale, 2012). The main reported complications are obstruction, vesicoureteric reflux, and persistent dilatation. Obstruction is initially managed by stenting because in some cases it is the result of postoperative edema. It also can be the result of ischemic structuring—especially after excisional tapering. In this case repeat ureteroneocystostomy is indicated, with the attendant risks associated with revision surgery. Conservative management of vesicoureteric reflux is warranted especially with the lower grades, because reflux has a tendency to resolve spontaneously in many cases. However, successful management with subureteric injection has been reported with minimal complication (DeFoor et al, 2004; Kitchens et al, 2006). Should subureteric injections fail, especially in cases of recurrent febrile UTIs, proceeding to revision surgery may be the only available option. A transureteroureterostomy may offer a valuable management option for repeat cases in unilateral affliction in which there is severe ureteral scarring or concerns regarding compromised blood supply.

Dilatation and Stenting

Endoscopic dilatation and stenting of the UVJ in POM has garnered increasing interest during the last decade or so. The method is less invasive than formal open or laparoscopic surgical intervention, with short- to medium-term success rates in the vicinity of 70% in most studies (Angerri et al, 2007; Carroll et al, 2010; Farrugia et al, 2011). However, the procedure is not without complications; stent migration, infection, hematuria, and stone formation have been reported in up to 31% of cases in one series (Farrugia et al, 2011). Furthermore, the need for repeat stenting, stenting by open surgical access in difficult cases, and ureteral injuries requiring emergent reimplantation may limit widespread use before long-term outcomes are documented (Carroll et al, 2010; Farrugia et al, 2011). In essence the ureteral orifice of the POM is accessed

endoscopically and dilated by a ureteral catheter or high-pressure balloon under fluoroscopic guidance until the indentation or waist-ing on the balloon disappears. Thereafter a double-pigtail catheter is left for 2 to 6 months before removal. Persistent dilatation or renal function deterioration at follow-up has successfully been treated by repeat stenting in some patients, whereas others have required reimplantation (Farrugia et al, 2014). Because long-term outcomes still are pending, patients need to be followed into adolescence (Christman et al, 2012).

Ureteral Strictures

Congenital ureteral strictures are rare anomalies that have been described causing hydroureteronephrosis. Dilatation is detected antenatally, but because of their extreme rarity these patients are usually misdiagnosed as having hydronephrosis or megaureter. Postnatal diagnostics with ultrasound, MRI, and retrograde pyelography subsequently usually confirm the diagnosis as being the result of a midureteral stricture. Management entails excision of the stenotic ureteral segment and reanastomosis by ureteroureterostomy; excised segments range in length from 1 to 3 cm and histologically are characterized by increased collagen deposition and muscular hypertrophy (Hwang et al, 2005; Brugnara et al, 2007).

Ureteral Polyps

Ureteral polyps are another rare anomaly that may lead to obstruction and dilatation. The polyps are most frequently seen in the upper third of the ureter and usually lead to UPJO. They are more common in males and on the left side, can be single or multiple, and can reach a size of several centimeters in diameter. Although they may cause antenatal dilatation, they tend to manifest symptomatically with pain and hematuria later in childhood because they exhibit slow growth and are benign. Diagnosis can be made by ultrasound, contrast-based CT scan, and MR urography. Confirmation usually is attained by retrograde pyelography or ureteroscopy. Management options include dismembered pyeloplasty with resection of the afflicted part of the ureter when polyps are near the UPJ or ureteral resection and ureteroureterostomy by open and even laparoscopic surgery. In cases of smaller polyps, ureteroscopic excision might be a feasible alternative. Histologically, they are classified as fibroepithelial benign polyps (Kanamori et al, 2010; Bian et al, 2011; Shive et al, 2012).

KEY POINTS: MEGAURETER

- The term *megaureter* is a descriptive one denoting dilatation of the ureter irrespective of cause.
- Megaureters have been subclassified into four categories based on causality: obstructed, refluxing, nonobstructed nonrefluxing, and refluxing with obstruction.
- The challenge is to prevent renal functional deterioration with either conservative or surgical treatment.
- Surgery is indicated in recurring UTIs, progressive unremitting dilatation on ultrasound, differential renal function less than 40%, and/or significant decreases in differential renal function of 5% or greater on sequential “comparable” renal nuclear functional studies.
- During the surgical procedure the stenotic distal part of the ureter is excised; the megaureter is straightened and then tapered to facilitate reimplantation in a nonrefluxing fashion with adequate ratio of length to diameter of 5:1 to improve coaptation of the ureteral lumen, whereby effective peristalsis and urine transportation are achieved.
- Most surgeons advocate temporary postoperative stenting.

Classification and Anatomic Description

Clinical Presentation

Evaluation

Clinical Management

Other Ureteral Anomalies

CLASSIFICATION AND ANATOMIC DESCRIPTION

General Patterns

Abnormalities of ureteral development, including ectopic ureters and ureteroceles, represent a large component of clinical urology and continue to challenge clinical management, despite their wide recognition and well-defined surgical strategies. The wide spectrum of involvement and the variable patterns of presentation underlie the clinical challenge and require a thorough understanding of both normal and abnormal embryology of the lower urinary tract. This chapter presents the clinical manifestations, embryologic pathology, and evaluation and management strategies for ectopic ureters and ureteroceles as well as other less common ureteral anomalies of formation. Obstructive ureteral pathologies including ureteropelvic junction obstruction (UPJO) and ureterovesical junction obstruction are reviewed in Chapter 132.

Although ectopic ureter and ureterocele are typically presented as distinct entities, it is apparent that they share many common features and may well have the same underlying developmental mechanisms, with slight variations that induce the very obvious differences in their appearances. In many ways, they may be approached in a similar manner, with slight variation in management because of their particular differences. It is also apparent that clinical cases may represent manifestations that lie between the two entities, suggesting a continuum of embryologic development.

Ectopic Ureter

By definition, an ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder. In a duplex system this is inevitably the upper pole ureter, presumably because of its budding from the mesonephric duct later than the lower pole with later incorporation into the developing urogenital sinus. If it is simply near the bladder neck, it is not technically ectopic, which requires entry at the level of the bladder neck or distal. In females, the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus, and even rectum (Fig. 134-1). It may be associated with a cyst of the Gartner duct, the remnant of the wolffian duct from which the ureter buds, and may include cystic dilation of the duct. The duct typically runs parallel to the vagina (the müllerian structure), and with rupture of the cystic ductal structure, communication with the vagina is established. This is the basis for incontinence, the frequent presentation of an ectopic ureter in females. In males, the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor, and usually into the wolffian structures, including vas deferens, seminal vesicles, or ejaculatory duct (Fig. 134-2; also see Fig. 134-1). Presentation in male patients does not involve incontinence, but

rather infection and pain of the affected organs (testicles and epididymis).

Single-system ectopic ureters and ureteroceles may manifest in a similar fashion but may also be associated with an apparently absent kidney. This usually reflects an inability to identify the kidney on typical imaging and has led to the use of computed tomography (CT) imaging with contrast to detect small, poorly functioning renal units associated with an ectopic ureter (Borer et al, 1998). Either single or duplex systems with an ectopic ureter may cause severe hydronephrosis reflecting distal obstruction. This may have impaired normal renal development to the point that the affected segment is nonfunctional, which needs to be clinically assessed.

The rare entity of bilateral single-system ectopic ureters may be associated with a hypoplastic bladder and bilateral renal abnormalities, typically dysplasia (Koyanagi et al, 1977; Noseworthy and Persky, 1982; Johnin et al, 2007). Some of these children may be considered to have bladder agenesis owing to the absence of a recognizable bladder structure, presumably because of the absence of bladder work in utero.

KEY POINTS: ECTOPIC URETER

- An ectopic ureter is any ureter, single or duplex, that does not enter the trigonal area of the bladder.
- In a duplex system the ectopic ureter is inevitably the upper pole ureter owing to its budding from the mesonephric duct later (more cephalad) than the lower pole ureteral bud.
- In females, the ectopic ureter may enter anywhere from the bladder neck to the perineum and into the vagina, uterus, and even rectum. One of the classic symptoms is continuous wetting.
- In males, the ectopic ureter always enters the urogenital system above the external sphincter or pelvic floor and usually into the wolffian structures, including vas deferens, seminal vesicles, or ejaculatory duct. Clinical presentation is not incontinence but infection.

Ureterocele

Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra. As with the ectopic ureter, ureteroceles may be associated with a single or duplex system, and in duplex systems are associated with the upper pole (Fig. 134-3). Ureteroceles can extend into the urethra but do not form entirely within the urethra, nor do they attach to the wolffian ductal structures.

Figure 134-1. Sites of ectopic ureteral orifices in the male and female.

Several classification systems exist for ureteroceles, but the most useful one for clinical practice separates intravesical from extravascular ureteroceles. The intravesical ureterocele is entirely within the bladder and above the bladder neck. This would include a “simple” ureterocele that may be seen in the adult with minimal dilation and mild to no upper tract dilation. This term, however, should be discouraged; the term *single intravesical ureterocele* should be used (Glassberg et al, 1984). An ectopic ureterocele includes those “in which some portion of the ureterocele is situated permanently at the bladder neck or urethra” (Glassberg et al, 1984). The orifice may be in the bladder, at the bladder neck, or in the urethra. This should be distinguished from an intravesical ureterocele that prolapses into the urethra with voiding.

Further descriptive subdivision of ureterocele types has been published, particularly by Stephens (Stephens, 1971; Stephens et al, 1996). These include cecoureterocele and stenotic, sphincteric, sphincterostenotic, blind, and nonobstructed ureteroceles (Fig. 134-4). From a clinical perspective, the most important subgroup to recognize is the cecoureteroceles. In these cases, the orifice of the affected ureter is within the bladder but the cavity of the ureterocele extends beyond the bladder neck into the urethra. These may not be readily identified preoperatively (Smith and Parrott, 1994), and their complexity may create surgical challenges, particularly with endoscopic incision (see later).

An unusual but diagnostically challenging ureterocele variant is the nonobstructive ureterocele with duplication (Bauer and Retik, 1978) or “ureterocele disproportion” (Share and Lebowitz, 1989) (Fig. 134-5). These are associated with a duplex kidney, but the affected upper pole is nondilated and typically dysplastic to such a degree that it is not readily detected on most imaging and the affected ureter is not dilated beyond the bladder. A typical appearing ureterocele is seen in the bladder, but the ipsilateral kidney appears completely normal.

Figure 134-2. Retrograde injection study of a boy with abdominal pain and a ureterocele associated with a hypoplastic right kidney. The intravesical ureterocele (UC) is being injected and demonstrates communication with the right seminal vesicle (arrowhead) and vas deferens (arrows), with the ureter (UR) leading to the dysplastic kidney. At surgical resection, the ureter and vas joined just above the seminal vesicles.

Figure 134-3. Diagram of intravesical ureter with stenotic orifice just proximal to the bladder neck.

Figure 134-4. A, Sphincterostenotic ectopic ureterocele. B, Cecoureterocele lumen extends distal to the orifice as a long tongue beneath the ureteral submucosa. The orifice communicates with the lumen of the bladder and is large and incompetent.

Figure 134-5. Ureterocele disproportion demonstrated via retrograde pyelography. Note the disparity between the large ureterocele and the thin ureter and nondilated collecting system.

There is some association of ureterocele type with outcomes of various therapeutic measures, but these have not proven to be as predictable as initially reported. Churchill and colleagues proposed a classification system based on the impact of the ureterocele on the upper urinary tract, including all renal units (Churchill et al, 1992). This functional system separates those in which the upper pole only is in jeopardy, those in which an entire ipsilateral kidney is threatened, and those in which the contralateral system is also at risk because of reflux or bladder outlet obstruction. The last group comprised 26% of the reported cases.

KEY POINTS: URETEROCELE

- Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra.
- Several classification systems exist for ureteroceles, but the most useful one for clinical practice separates intravesical from extravesical ureteroceles.
- In a cecoureterocele, the orifice of the affected ureter is within the bladder but the cavity of the ureterocele extends beyond the bladder neck into the urethra.

Embryology and Etiology

The specific mechanisms responsible for ectopic ureters and ureteroceles remain undefined, but our emerging understanding of normal and abnormal ureterotrigonal development, with new investigational tools, is likely to provide valuable insights (Mendelsohn, 2009). These molecular mechanisms will be of scientific importance, but they will also permit potential separation among variants of these conditions with therapeutic relevance, as well as ultimately permitting early detection (i.e., in utero) and intervention. The last is a distant but not implausible horizon. At present, we remain uncertain as to fundamental mechanisms yet need to

know which ureteroceles and ectopic ureters may be associated with bladder neck and trigonal maldevelopment sufficient to cause functional disturbances such as incontinence. These children will require more aggressive therapy to achieve continence. Early identification may permit earlier and more effective surgical therapies.

Clinical Relevance

Understanding the potential relationships of the abnormal ureter associated with ectopia or a ureterocele, which occurs because of aberrations in normal development of wolffian and müllerian ducts, ureteral bud, urogenital sinus, and bladder, can facilitate clinical interpretation of these conditions. Knowledge of the sites of ectopic insertion may be useful in planning imaging and surgical correction. Recognition of the possible effects of abnormal ureteral development on bladder and urethral development is essential in determining reconstructive strategies, and an awareness of the possible coexistence of ureteral and müllerian abnormalities is important.

Ureteral-Trigonal-Renal Development

The pathogenesis of ureteral ectopia with or without ureterocele results in renal maldevelopment caused by defective ureterotrigonal connections. At present, a growing number of genetic pathways have been identified that are critical in humans and rodents for establishing distal ureter connections, and studies in mouse models have led to a better understanding of the process by which proper distal ureter connections are generated.

Function of the urinary tract depends on patent ureterobladder connections and an antireflux mechanism that prevents backflow of urine to the ureter and kidneys. The antireflux valve is formed by intersecting ureteral and bladder muscle fibers, hence malpositioned ureters that do not follow a precise trajectory through the bladder wall or terminate outside the normal insertion site in the trigone can cause obstruction or vesicoureteral reflux (VUR). Renal defects associated with ureteral ectopia, ureterocele, or VUR can be caused by obstruction that damages renal cell types (see Chapter 132) or mutations in genes that are required independently for normal kidney development and ureter insertion, including *Ret*, *Fgfr2*, *Gata3* and a number of others (Chia et al, 2011; Liu et al, 2011; Hoshi et al, 2012).

Classic understanding of ureterotrigonal development suggests that the trigone originates from the mesodermal common nephric duct (CND), as do the mesonephric duct and ureter, and is distinct from the urogenital sinus, which is of endodermal origin. According to this model, proper ureterobladder connections depend on expansion of the CND and its subsequent insertion into the urogenital sinus epithelium (UGE), both separating the CND and ureter and producing a mature insertion site in the bladder (Wesson, 1920; Tanagho and Pugh, 1963; Woodburne, 1965). However, the observation that the CND degenerates during ureter maturation suggests that it may not give rise to the trigone as previously thought (Batourina et al, 2002, 2005; Viana et al, 2007; Chi et al, 2009; Mendelsohn, 2009; Uetani et al, 2009; Tanaka et al, 2010). Consistent with this, lineage studies and tissue recombination studies in mice suggest that the trigone is formed by interconnections between the detrusor and fibers surrounding the intravesical ureter (Viana et al, 2007).

With ureteral bud formation, the mesonephric duct becomes the CND caudally towards the insertion into the urogenital sinus. Studies in animal models indicate that establishing a mature ureterobladder connection depends on a process of ureteral maturation, a complex series of events driven by cellular rearrangements and apoptosis of the CND. Ureteral maturation begins when the most distal portion of the CND begins to merge with the urogenital sinus and undergoes apoptosis, which occurs over the course of several days. This first round of apoptosis results in removal of the most distal portion of the CND and formation of a loop composed of the remaining CND and distal ureter. The loop makes contact with the dorsal UGE, an event that sets the position of the future

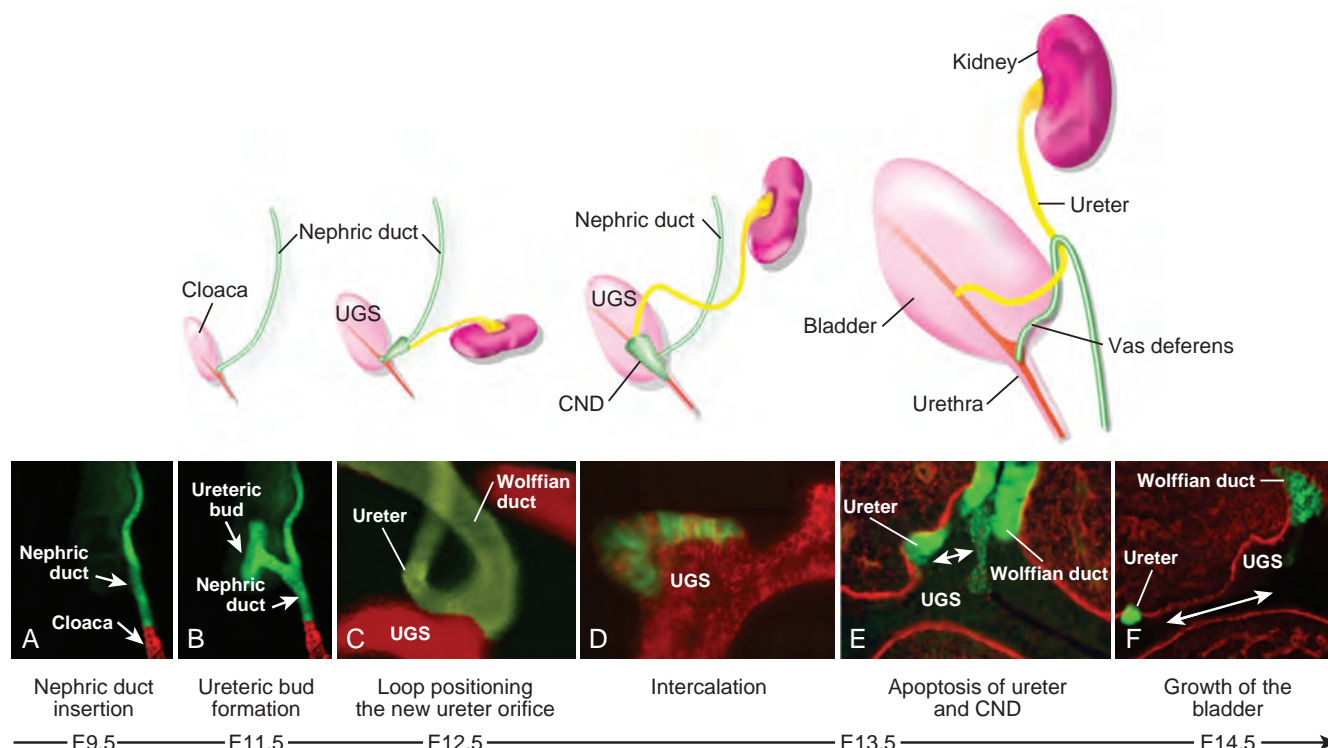

Figure 134-6. *Top*, Schematic drawing showing a revised model of ureter maturation. *Bottom*, Images of *Hoxb7-GFP* expressing embryos showing different stages of urinary tract morphogenesis. In the lower urinary tract, the *Hoxb7-GFP* transgene is localized in the ureter, mesonephric (wolffian) duct, and common nephric duct (CND) (Srinivas et al, 1999). **A**, Whole mount urogenital tract from an E9 *Hoxb7-GFP* embryo counterstained with E-cadherin to reveal the mesonephric duct (green) inserting into the primitive bladder (red). **B**, A whole mount urogenital tract from an E11 *Hoxb7-GFP* embryo counterstained with E-cadherin (red). The CND lies below the primary ureteric bud branch, which at this stage has invaded the kidney blastema (not visible). **C**, Whole mount urogenital tract from an E12 *Hoxb7-GFP* embryo (green) stained with cytokeratin (red). Apoptosis of the CND has brought the caudal-most ureter into close contact with the bladder, where it aligns, setting the position of the future ureteral orifice. **D**, A vibratome section from an E13 *Hoxb7-GFP* urogenital tract stained with E-cadherin (red). Cells from the most distal ureter epithelium have now merged with the bladder epithelium, where they will undergo apoptosis, creating a new ureteral bud connection. **E**, A whole mount urogenital tract from an E13.5 *Hoxb7-GFP* embryo stained with laminin to reveal the basement membrane of the bladder epithelium (red). The ureter orifice is now inserted in the epithelium and is separated from the mesonephric duct by a short distance. **F**, Expansion and elongation of the bladder has moved the ureter orifice farther away from the mesonephric (wolffian) duct. UGS, urogenital sinus.

ureter orifice. Merger of the loop with the UGE and removal of the remaining CND by apoptosis generates a patent connection between the ureter and bladder, which at this stage is at the level of the verumontanum (Fig. 134-6). Subsequent growth and expansion of the bladder and urethra further separate the mesonephric duct and distal ureter. The ureter is initially occluded by cells that undergo apoptosis shortly before birth (Mendelsohn, 2009). These cells may correspond to the Chwalle membrane, which in humans is thought to be important for generating a patent ureterobladder connection, which if abnormal, can result in ureterocele (Chwalle, 1927).

Studies in mouse models suggest that ectopic ureters can arise from defects that cause misalignment of the loop with the dorsal side of the urogenital sinus, altering the position where the ureteral orifice inserts. Potential events include delayed or defective nephric duct insertion into the cloaca, sprouting of the primary ureteric bud from an abnormally high or low position on the nephric duct relative to the urogenital sinus, and defective ureteral maturation. A ureter that inserts in the proper site but is obstructed may reflect failure in regression of the Chwalle membrane. The revised model of ureteral maturation provides possible mechanisms for ureteral ectopia and ureterocele formation. Abnormal apoptosis may maintain the connection between the ureter and the wolffian duct and

prevent incorporation of the ureter and the urogenital sinus. This defect would produce a ureter attached to the wolffian remnants in girls (Gartner duct) or to the vas deferens or ejaculatory system in boys. Alternately, partial CND regression may result in ureters that join the bladder at an abnormally posterior site, close to or in the urethra.

In duplicated systems, upper pole kidneys derived from ureteric bud branches that formed at an abnormally high position on the mesonephric duct tend to be obstructed, whereas distal ureteral obstruction is rare in lower-pole renal moieties that arise from ureteric bud branches that sprout from the mesonephric duct at the appropriate site. This upper pole defect may reflect incomplete CND remodeling, a suggestion supported by observations from mouse models with duplicated systems. In this case, CNDs associated with ureters that form at an abnormally anterior site on the mesonephric duct persist, resulting in obstruction, whereas CNDs associated with ureters that form at the proper site, close to the urogenital sinus, undergo regression. These observations together suggest that signals from the urogenital sinus may normally regulate ureteral maturation by controlling CND remodeling.

These observations suggest that the final position of the ureter depends in large part on the extent of CND remodeling, which can

be disrupted by defects in cell movements or apoptosis. If there is no remodeling, the ureter will remain joined to the sex duct (ectopic vas deferens or Gartner duct in girls). Partial CND remodeling could produce a different defect. In this case, distal ureters will be joined to the urogenital sinus at a site that is closer to the nephric duct, which joins at the level of the verumontanum or sinus ridge. Very similar defects are observed in mouse models, including mutants lacking *Ret*. Mutations in *RET* in humans cause Hirschsprung disease, renal abnormalities, VUR, and hydronephrosis. Studies in *Ret*-mutant mice indicate that *Ret* controls ureteric bud formation as well as mesonephric duct insertion and CND regression, suggesting that conserved genetic pathways may be required at independent sites and at different stages for generating a normal urinary system.

Obstruction is unlikely to be a major, and certainly not the only, factor producing ureteral dilation as seen with ureteroceles. Ureteroceles with large orifices and no apparent obstruction are well recognized clinically. Ectopic ureters with insertion into the bladder neck are dilated, but do not have the disproportionate distal dilation characteristic of the ureterocele. Obstruction plays some role in ureterocele pathophysiology, however, as is evident in the frequent occurrence of decompression with ureterocele puncture. Whether this is determined by the degree of muscularization of the ureterocele is undefined. Recent studies support the idea that degeneration of the Chwalle membrane (Chwalle, 1927) is important for generating a patent connection between the ureter orifice and the bladder (Mendelsohn, 2009). These studies suggest that the Chwalle membrane, which has been thought to form from the urogenital sinus, may in fact be derived from luminal cells in the ureter that undergo apoptosis at a relatively late stage, before the onset of renal function, which may be important for generating a patent connection between the distal ureter and bladder.

KEY POINTS: EMBRYOLOGY

- In contrast to the classic model in which the CND forms the trigone, the revised model includes regression of the CND in the normal animal through apoptosis and formation of the trigone from the endoderm, like the bladder.
- The classic explanation of ureterocele formation is that of Chwalle, who postulated that distal ureteral expansion is produced by failure of rupture of a distal membrane at the ureteral orifice (Chwalle membrane).
- Because the ureteral bud derives from the wolffian duct, the ectopic ureter will not insert directly into the müllerian structures (vagina, cervix, uterus), but will be associated with them through the remnant of the wolffian duct, the Gartner duct, that runs alongside the mature müllerian structures.
- The Weigert-Meyer rule describes the inverse relationship of the duplex ureteral orifices, in which the ectopic ureter or ureterocele associated with the upper pole is caudal to the lower pole ureteral orifice.

CLINICAL PRESENTATION

Imaging

Prenatal Detection

The majority of ureteroceles and ectopic ureters are detected through prenatal ultrasound imaging, even if the specific diagnosis is not made. The abnormality prompts postnatal imaging, which will invariably determine the specific cause, lead to further studies, and permit an adequate characterization of the condition. The prenatal imaging patterns are identical to those seen postnatally on ultrasound imaging, yet may be misinterpreted. While these are described in the chapter on prenatal diagnosis (Chapter 124), several elements should be emphasized.

The identification of a duplex system prenatally may be difficult except when one of the moieties is dilated. The report of an upper pole “cyst” in a fetus should be interpreted as being upper pole

hydronephrosis until proven otherwise. Minor degrees of hydronephrosis may not be as readily identified, although changes over time may prompt recognition. The expected ureteral dilation may not be readily detected but can be traced to the bladder. The bladder must be inspected in all such cases to identify a ureterocele, but it may be required to await bladder filling to make this observation. A large ureterocele can fill a bladder and mask its presence.

The character of the renal parenchyma of the upper pole should be noted, both thickness and echogenicity. The findings should never be used alone to determine salvageability of the upper pole but may be useful in making clinical decisions.

The ectopic ureter can appear identical to a ureterocele except at the bladder level, with a dilated upper pole, tortuous ureter, but no intravesical component. On occasion, a large ectopic ureter may impinge on the bladder and appear as an intravesical structure, termed a *pseudoureterocele* (Sumfest et al, 1995). These patterns are identical to the postnatal appearance, but their recognition does require an experienced maternal-fetal ultrasonographer.

With a tentative diagnosis of a ureterocele or ectopic ureter, careful evaluation of the other renal units and bladder should be made. Ipsilateral lower pole or contralateral dilation suggests reflux or less commonly obstruction from the ureterocele or the dilated ectopic ureter. Bladder outlet obstruction by a ureterocele can occur and manifest as hydronephrosis of all renal units (Ogunyemi, 2001; Quintero et al, 2001; Godinho et al, 2013). Although it is very unusual to identify bladder obstruction from a ureterocele to the extent to produce oligohydramnios, this can occur. Contralateral renal dysplasia may be evident and associated with reduced amniotic fluid. The need for prenatal intervention or early delivery is exceptional and unlikely to provide any significant benefit.

A single-system ureterocele or ectopic ureter will be evident with dilation of the entire kidney as well as ureter. It may be impossible to differentiate this from an obstructive megaureter or severe reflux, but this will have little immediate prenatal clinical impact.

Incidental

When significant hydronephrosis is present with either an ectopic ureter or ureterocele, an incidental diagnosis will occasionally be made. In some cases, however, this may result from a search for an explanation of general abdominal pain that was not considered to have a renal cause. It is also possible that the dilated ureter may not be recognized as such, and cases of presumed ovarian cysts have been seen that were actually markedly dilated ureters (Mason et al, 2012).

Infection

Infection remains a significant reason for clinical presentation of both ectopic ureters and ureteroceles, which may occur at any age and have a highly variable pattern.

Clinical Patterns: Highly Variable

Although there is great variability in the presentation of either ectopic ureter or ureterocele, there are several patterns that may be anticipated. In either case, generalized urosepsis may be the presenting clinical scenario, and a renal bladder ultrasound will usually provide the diagnosis. It has been reported that an acute ultrasound study is unnecessary if a child has a febrile urinary tract infection (UTI) and a history of a normal prenatal ultrasound examination after 30 to 32 weeks (Hoberman et al, 2003). The extreme variability of quality of prenatal imaging makes this recommendation tenuous, and it would seem prudent that an ultrasound study be obtained in all children with urosepsis. In those with a febrile UTI, there is rarely urgency if they are clinically responding. The value of early detection is the potential for early treatment, which may be a simple drainage procedure. If the child is recovering rapidly, imaging may be elective.

In the acute setting, with evidence of an ectopic ureter or ureterocele, initial clinical response will determine the timing of

intervention (discussed later). Certainly the child with sepsis who is not responding rapidly to appropriate therapy may require urgent transurethral incision (TUI) of an infected ureterocele, or percutaneous or open drainage of an ectopic ureter. Open drainage in this setting is often an end ureterostomy as described later.

Ectopic ureters will frequently manifest with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, a negative urine culture will be present simply because the infected ectopic system is not draining into the bladder. Parents may describe a purulent discharge from the perineum ([See and Mayo, 1991](#)). This clinical pattern should prompt an ultrasound study, which will usually reveal a dilated upper pole or entire system. It is rare for the unobstructed ectopic ureter to manifest with infection, but it is associated with incontinence.

In boys, a similar generalized subacute pattern of infection may be present, but more often these boys have epididymitis on presentation. Although this may be an unusual subset of young boys with an acute scrotum, they will have a true bacterial epididymitis and may or may not have infected urine. In the setting of a suspicion for epididymitis in a young boy, it is prudent to perform a brief ultrasound examination of the upper tracts to ensure no abnormality ([Rajfer et al, 1978](#); [Umeyama et al, 1985](#); [Chu et al, 2012](#)). Older males will also present in this manner, although it is unclear why it may be so delayed. Some have had recurrent episodes of epididymitis before the underlying cause is detected.

Incontinence

Clinical Patterns

Urinary incontinence may be caused by an ectopic ureter in a girl, but not in a boy. Untreated ureteroceles are not associated with incontinence. The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter. Imaging studies may not immediately detect this condition because the affected renal moiety may not be dilated, and the level of suspicion must be guided by a careful history and occasionally physical examination. Before toilet training it may be difficult to detect continuous incontinence, although some parents will note persistent dribbling during changing. In early training, the wetting may be falsely attributed to lack of motivation. Persistence will usually prompt evaluation, and the characteristic history can be obtained. This is usually one of persistent low-volume dampness at all time. When asked if the child can be dry for 30 to 60 minutes, the parent will usually say no. It is important to be cautious in questioning, because some parents with children who wet for other reasons may state, "She is always wet," when in fact the child can be dry for periods of time. The dampness associated with an ectopic ureter typically occurs throughout the day and does not relent. It may seem to be worse with activity in some. In rare patients it has been intermittent, perhaps caused by intermittent leakage through a membrane of Gartner duct.

In older children in whom the diagnosis has not been recognized, attribution of the symptoms may be to dysfunctional voiding, laziness, and even sexual abuse ([Lane, 1962](#); [Carrico and Lebowitz, 1998](#)). During the history taking, signs of typical voiding dysfunction such as voiding postponement, posturing, and constipation should be sought to assess likelihood of these being an explanation for the wetting.

Pain

Pain is uncommonly associated with either an ectopic ureter or a ureterocele. The exceptions are acute infection, and also episodic obstruction of the ectopic ureter or bladder pain caused by an obstructing ureterocele. Occasional cases of intermittent drainage of an ectopic ureter in older children have been experienced and are characterized by abdominal pain followed by perineal drainage of urine or purulent material. It is presumed that this reflects accumulation of urine in a system that is obstructed at the level of the orifice with subsequent drainage and relief of symptoms.

Figure 134-7. A prolapsed ureterocele presented as an interlabial mass in a 3-week-old girl.

Prolapse

Ureterocele prolapse is an unusual but distinctive presenting sign that may still confuse the clinician. These are usually smooth, congested mucosal-covered intralabial masses, and the child may be experiencing difficulty voiding. The mass protrudes from the urethra, distinct from the vagina, and is not circumferential as a urethral prolapse would be. It is not lobulated as a sarcoma botryoides would appear. An ultrasound examination of the bladder will usually confirm the diagnosis, and kidney images will further support this ([Fig. 134-7](#)).

Late Presentation

Presentation of both ectopic ureters and ureteroceles in the teen or adult has been reported, usually associated with infection or abdominal pain and rarely incontinence ([Idbohrn and Sjostedt, 1954](#); [Abrahamsson et al, 1981](#); [Amitai et al, 1992](#); [Westesson and Goldman, 2013](#)). The nonobstructing ureterocele, often associated with a single system, is well recognized in the adult, often with a stone in the small ureterocele ([Singh, 2007](#); [Mizuno et al, 2008](#)). Vaginal wall prolapse has also been associated with an ectopic ureter ([Chai et al, 2014](#)). In most cases of late presentation, upper pole nephrectomy may be the most appropriate management because there is usually little to no function associated with the affected renal moiety ([Brehmer et al, 2007](#); [Mason et al, 2012](#)).

KEY POINTS: CLINICAL PRESENTATION

- The majority of ureteroceles and ectopic ureters are detected through prenatal ultrasound imaging, even if the specific diagnosis is not made until after birth.
- Ectopic ureters will frequently manifest with a less acute pattern evidenced by ongoing low-grade fever with periodic spikes. In some cases, urine cultures will be negative because the infected ectopic system is not draining into the bladder.
- In boys, a similar subacute pattern of infection may be present, but more often these boys have epididymitis.
- Urinary incontinence may be caused by an ectopic ureter in a girl but not in a boy.
- The toilet-trained girl with verified continuous urinary leakage must be evaluated for an ectopic ureter.
- Ureterocele prolapse is an unusual but distinctive presenting sign; these are usually smooth, congested mucosa-covered intralabial masses, and the child may be experiencing difficulty voiding.

EVALUATION

Management of ectopic ureter or ureterocele is based on a thorough assessment of the affected anatomy and the functional implications of the condition. This may usually be obtained readily but in some cases will require more involved imaging such as magnetic resonance urography.

Anatomic Assessment

Physical Examination

With both ectopic ureter and ureterocele, physical findings may facilitate diagnosis. The prolapsed ureterocele is diagnostic and dramatic, but unusual. Further study of the detailed anatomy is necessary. It is unusual to be able to detect an ectopic perineal ureteral orifice in a child, but this will provide much information as to the character of the situation and best treatment (Fig. 134-8). A search for the perineal orifice in a child with continuous wetting or a

Figure 134-8. Perineal ectopic ureteral orifice (*bottom arrow*) cannulated with an angiocatheter, situated between the urethral orifice (*top arrow*) and the vagina, just to the left of midline.

known leaking ectopic ureter is worthwhile. Rarely, the dilated Gartner duct cyst may be detected on careful perineal examination (Fig. 134-9). These orifices or cystic structures may then be imaged by injection of contrast.

The dilated upper pole of either an ectopic ureter or ureterocele may be palpable in the relaxed infant, but this is difficult in the older child.

Ultrasound

The ultrasound image will usually provide the anatomic diagnosis and permit inference of functional assessment. **The typical findings are as with the prenatal imaging of a dilated upper pole with ureteral dilation or a dilated single system.** The character of the renal parenchyma will be more readily seen postnatally and if it appears healthy, the true need for functional upper tract imaging can be questioned. Depending on the chosen treatment algorithm, it may be argued that this is unnecessary, as it will not change treatment. The difference between functioning upper poles and those with little to no function is usually apparent (Figs. 134-10 and 134-11).

There are no characteristics that permit differentiation between a dilated ectopic ureter and ureterocele above the bladder. **The bladder images therefore become critically important because management is very different.**

Bladder views should be diagnostic to differentiate ureterocele from ectopic ureter by revealing a thin-walled, cystic dilation within the bladder and not extending beyond its walls (Fig. 134-12). The laterality of the ureterocele is usually apparent but may appear midline if large. A lobulated ureterocele may appear as two structures, but careful examination should show communication. It is difficult to visualize extension of a cecoureterocele into the bladder neck, so nonvisualization is not diagnostic.

Several ultrasound patterns may produce confusion in diagnosis. A large ureterocele may completely fill a bladder with no urine in the bladder itself. A full bladder with an effaced ureterocele may be mistakenly considered an ectopic ureter. Observation of the bladder over time will usually avoid these errors. A very dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele, as noted in fetal diagnosis, but the wall will be bilaminar and much thicker than typically seen with a ureterocele (Fig. 134-13). Furthermore, the lumen of the ectopic ureter will extend well outside the bladder walls.

Figure 134-9. A, Gartner duct cyst (*bottom right arrow*) in newborn with a left multicystic dysplastic kidney. B, Injection of the cyst communicated with the ureter and dysplastic kidney.

Figure 134-10. Ultrasound image of dilated upper pole (UP) associated with a ureterocele, demonstrating limited renal parenchyma (same patient as in Fig. 134-34). LP, lower pole.

Figure 134-11. Ultrasound demonstrating dilated upper pole (UP) and lower pole (LP) associated with a ureterocele. The upper pole has evident renal parenchyma. The lower pole is dilated because of compression of the dilated upper pole ureter on the lower pole system, creating a partial obstruction.

Figure 134-12. Ultrasound image of an intravesical ureterocele at the bladder level.

Magnetic Resonance Imaging

Magnetic resonance urography can provide the most detailed images of an affected urinary tract, as a whole with functional information, yet is rarely useful to provide data that may be obtained with less expensive methods not requiring sedation. Eventually, magnetic resonance imaging (MRI) is likely to become the modality of choice, however. At present its value rests with patients in whom other imaging cannot define complex anatomy. This may occur with massive dilation in which the existence of duplication may be uncertain, or in which anatomic relationships are significantly distorted (Fig. 134-14). If this type of anatomic delineation is needed, MRI offers the addition of functional information that is an equally important aspect of evaluation. The sensitivity of MRI may also be useful in detecting the occult duplication with an ectopic ureter (Fig. 134-15).

Functional Assessment

Functional urinary assessment in association with an ectopic ureter or ureterocele is the foundation for both initial management and postoperative care. Both renal and bladder function are affected by the developmental abnormalities of ureteral formation and may ultimately require complex surgical interventions.

Renal Function

Nuclear Imaging. Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best afforded by dimercaptosuccinic acid (DMSA) imaging. (Fig. 134-16) The function of the affected upper pole is the principal focus, but the health of the other renal moieties must be determined as well, particularly if there is lower pole reflux or hydronephrosis of any unit. Although there have been some attempts to define what the “normal” function of an upper pole associated with an ectopic ureter or ureterocele should be, there are no criteria to define this. The clinical impact comes with the decision to preserve the upper tract or not, yet there are no objective parameters to determine what level of functional contribution should be preserved. The functional assessment therefore offers the dichotomy of some function versus no function, and this may or may not determine clinical management (see later). In general, this is clear, but there will always be ambiguous cases. Preoperative assessment is further confused by the lack of ability to predict the effect of decompression.

The assessment of drainage function for ureteroceles in which an observational approach may be considered is best accomplished with a diuretic renal scan (Han et al, 2005), which would then replace the DMSA scan. This provides both functional and drainage measurements. This has been shown to be of some clinical value in ureteroceles in which drainage is adequate, and ultimate resolution of the hydronephrosis has been reported (Han et al, 2005). A dilated ectopic ureter is only rarely suitable for observational management, so the value of an assessment of obstruction is limited.

Intravenous Pyelogram. In unusual situations the intravenous pyelogram (IVP) may offer adequate functional information with anatomic delineation without the complexities of an MRI. Functional assessment is only qualitative, however, and the IVP is a less useful baseline study except when the anatomy is uncertain or there is uncertainty about an ectopic ureter with no dilation in the setting of incontinence (Fig. 134-17).

Bladder Function

Although the bladder is not the principal focus of clinical attention in the evaluation of the ectopic ureter or ureterocele, the potential for impaired bladder function cannot be ignored. This may be caused by bladder outlet obstruction from a ureterocele, or impaired continence resulting from inadequate bladder neck function with an ectopic ureter or ureterocele. In the extreme case of bilateral single-system ectopic ureters, bladder development may be severely impaired because of the absence of fetal bladder filling.

Figure 134-13. A, Ultrasound image of bladder in a child with an ectopic ureter extending into the bladder. The wall of the ureter is thicker than a ureterocele, and the lumen of the ureter extends well outside the bladder lumen, indicating that this is an ectopic ureter rather than a ureterocele. B, Voiding cystourethrogram of a large ectopic ureter pushing inward on the back of the bladder and appearing as a filling defect in the bladder (pseudoureterocele). (B, Courtesy Dr. Jeanne Chow, Assistant Professor of Radiology, Harvard Medical School and Children's Hospital Boston.)

Figure 134-14. Use of magnetic resonance imaging to define the complex anatomy of a child with an ectopic ureter associated with a right dysplastic, cystic kidney (arrow) draining into an obstructed hemivagina and producing urinary dilation of the right hemiuterus. Initial therapy constituted creating a distal window between the two vaginae. Subsequently she underwent right nephrectomy.

Ultrasound Imaging Interpretation

A simple bladder ultrasound image may be very useful in completing the functional evaluation of these patients. Perhaps requiring some patience, waiting for bladder filling and emptying will yield information on bladder capacity emptying efficiency and bladder

Figure 134-15. Magnetic resonance urography demonstrating the presence of an occult upper pole associated with an ectopic ureter producing incontinence. The left upper pole ureter is marked by the arrow at the level of the lower pole pelvis.

wall thickness (indicative of possible outlet obstruction). The character, location, and size of the ureterocele can usually be assessed as well (see Fig. 134-12). In some cases, the ectopic nature of a dilated ureter may be identified ultrasonographically.

Voiding Cystourethrogram

The voiding cystourethrogram (VCUG) provides the most definitive evaluation of the bladder and distal ureters, as well as the urethra in ureteroceles and ectopic ureters, and is an obligatory imaging test (Fig. 134-18). This should almost always be obtained before any intervention to define the baseline situation. The unusual situation in which a VCUG may not be obtained would be if decompression of a ureterocele producing bladder outlet obstruction or severe bilateral upper tract obstruction in an infant is urgently indicated. It is unlikely that the findings on VCUG would alter treatment, which would nearly always be transurethral puncture.

Figure 134-16. A, Dimercaptosuccinic acid renal scan in a child with a left ureterocele demonstrating no function in the affected upper pole. B, Dimercaptosuccinic acid renal scan in a child with a ureterocele with evidence of upper pole function after transurethral incision to decompress the ureterocele. The upper pole was separately assessed as contributing approximately 18% of total renal function.

Reflux

The presence of reflux may determine initial treatment for some practitioners and is an important parameter in clinical management after initial decompression of the ureterocele. In the setting of an ectopic ureter, ipsilateral lower pole reflux is unlikely to resolve spontaneously and will determine definitive treatment options.

After incision of a ureterocele, the presence of reflux either ipsilaterally or contralaterally will be critical in therapeutic decision making.

Ureterocele and Bladder Outlet

The appearance of the bladder base with filling and voiding demonstrated on VCUG will also be useful in therapeutic decisions, because significant eversion indicates a weak trigonal floor that may be more likely to require surgical repair. Prolapse of a ureterocele into the urethra or demonstration of a cecoureterocele is an important factor in planning and performing a TUI and may be more predictive of the subsequent need for secondary surgery. The usual descriptive terms in the context of a ureterocele include *prolapse*, which is movement of the ureterocele into the urethra, *eversion*, or *diverticulum-like protrusion* of the bladder base and trigone

Figure 134-17. Intravenous pyelogram image of a 10-year-old child with lifelong wetting and evidence of ureteral duplication (*black arrow—upper pole*) with no hydronephrosis. The distal ureter (*white arrow*) can be seen passing by the bladder and bladder neck and inserting into the urethra near the perineum.

Figure 134-18. Voiding cystourethrogram image of child with a ureterocele appearing as a filling defect within the bladder and massive ipsilateral lower pole reflux.

with filling and voiding (Fig. 134-19), and *intussusception*, or protrusion of the ureterocele back into its ureter (Fig. 134-20).

Although it is difficult to predict continence at initial presentation, the ureterocele or ectopic ureter associated with a patulous bladder neck may be complicated by later urinary incontinence.

Figure 134-19. Voiding cystourethrogram of child with ureterocele and evidence of prolapse of the ureterocele into the bladder neck with voiding. This is distinct from a cecoureterocele, in which the ureterocele is part of the urethra. This pattern of prolapse can cause bladder outlet obstruction.

Figure 134-20. Voiding cystourethrogram in a child with a ureterocele and evidence of ureterocele eversion with voiding. The apparent diverticulum is the ureterocele extending outside the bladder wall with increased intravesical pressure. This pattern may be seen with the ureterocele everting or intussuscepting into its dilated ureter. There is lower pole reflux as well.

Cecoureteroceles are of particular risk, but we have also observed bladder neck ectopic ureters with wide-open bladder necks and later incontinence after resection of the distal ectopic ureter and external bladder neck reinforcement (Fig. 134-21). These patients may benefit from more aggressive bladder neck tightening at the time of definitive resection of the ureterocele or ectopic ureter; however, this entails some risk of disturbing what may be normal bladder neck function. Video-urodynamic evaluation may be helpful in such patients.

Figure 134-21. Voiding cystourethrogram image of a cecoureterocele where the ureterocele (black arrow) is attached to the urethra (white arrow) and the lumen extends into the urethra. These are the most challenging ureteroceles owing to the involvement of the bladder neck and urethra.

Endoscopic Evaluation

The final element of evaluation of a ureterocele or ectopic ureter can be endoscopic. Although this is not always essential, most cases of both ureterocele and ectopic ureter will come to operative intervention, and concurrent endoscopic evaluation is important if not essential. Certainly when endoscopic incision is to be performed, this is a critical element and should be performed thoroughly before incision to permit selection of the most effective site.

Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter. The location of the other ureteral orifices should be documented. The orifice of the affected ureter should be sought but may not be identified. The urethra is examined carefully for the orifice if not seen in the bladder. The appearance of the ureterocele will vary with bladder filling, and it is best to start with little filling and slowly increase bladder volume (Fig. 134-22). The ureterocele will be seen to slowly flatten. Its true limits are best appreciated with limited bladder filling; this will expose the lowest portion, which is probably the best site for incision. Extension of the ureterocele into the urethra, indicative of a cecoureterocele, may be detected, and this would indicate the need to make sure this section does not cause obstruction with incision. Retrograde contrast injection can confirm the presence of ureterocele disproportion, as there will be only a narrow proximal ureter and no filling of an upper pole segment (see Fig. 134-5). Unusual connections with the genital ducts may also be demonstrated as in the example of a boy with a ureterocele and communication among the ureter, vas deferens, and seminal vesicles (see Fig. 134-2).

An ectopic ureteral orifice may be very difficult to find endoscopically, but if in the bladder neck it is often patulous (Fig. 134-23). The anatomic connections of the ectopic ureter may be demonstrated using retrograde contrast studies. We have identified ectopic ureters that appear to have a very thin layer of tissue separating them from the urethra, looking much more like a ureterocele than an ectopic ureter (Fig. 134-24A and B). These may be associated with defects in the bladder neck and incontinence

Figure 134-22. Endoscopic image of an intravesical ureterocele just inside the bladder neck.

Figure 134-23. Endoscopic views of the bladder neck and the ectopic ureteral orifice marked by the *arrow*. Bladder neck ectopic ureteral orifices are often patulous but do not always reflux.

Figure 134-24. **A,** Endoscopic images of the bladder neck orifices of an ectopic ureter with an appearance similar to that of a ureterocele without the dilated intravesical portion. The membrane overlying the orifice was thin and fluttered with irrigation, just as a ureterocele would be. **B,** At open surgery, these bladder neck ectopic ureters can have the appearance of a defect in the bladder neck (*arrow*) and be associated with incontinence. It remains unclear how these ectopic ureters are related to ureteroceles.

(Fig. 134-24C). Consideration for more extensive removal of these patulous segments with reconstruction of the bladder neck may be part of the clinical decision, and their endoscopic appearance can facilitate this decision.

KEY POINTS: EVALUATION OF ECTOPIC URETERS AND URETEROCELES

- The ultrasound image will usually provide the anatomic diagnosis of an ectopic ureter or ureterocele and permit an inference of renal function.
- The typical findings are of a dilated upper pole with ureteral dilation or a dilated single system.
- The ureterocele is characterized by a thin-walled, cystic dilation within the bladder and not extending beyond its walls.
- A very dilated ectopic ureter may produce an impression on the bladder and appear as a ureterocele.
- Radionuclide renal imaging remains the gold standard for renal functional assessment, and this is usually best provided by DMSA imaging.
- The function of the affected upper pole is the principal focus, but the health of the other renal moieties must be determined as well.
- VCUG provides the most definitive evaluation of the bladder and distal ureters, as well as the urethra.
- The appearance of the bladder base with filling and voiding demonstrated on VCUG will also be useful in therapeutic decisions, as massive eversion indicates a weak trigonal floor that may be more likely to require surgical repair.
- Endoscopy should take note of the character of the urethra, bladder neck, and trigone relative to the ureterocele or ectopic ureter.

CLINICAL MANAGEMENT

Management Goals

It should once again be stressed that, before any surgical intervention for ectopic ureters or ureteroceles, the surgeon must obtain as much information as possible regarding the patient's altered anatomy and physiology. Only then can a rational treatment plan be devised. Although specific and definitive management for ectopic ureters and ureteroceles differs in some individuals, the goals of management are the same, and in many cases the approaches are identical.

The goals of therapy should be clearly defined and factored into the clinical decisions. These goals are **preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence**. Minimizing surgical morbidity is a goal that must be included in this consideration. Although the goals of treatment are generally agreed on, the means to achieving those goals remain controversial. One area of at least partial agreement is that early institution of daily prophylactic antibiotics can reduce the risk of UTIs in those patients in whom there is significant hydronephrosis.

Relieve Obstruction, Prevent Reflux, Maintain Continence

For both ectopic ureter and ureterocele associated with a duplicated system, a primary concern is the preservation of functional renal parenchyma if at all possible. This goal is achieved by **correcting obstruction and preventing reflux with its risks of renal parenchymal damage from infection** (Churchill et al, 1992). At times it is necessary to balance one against the other, because relieving the obstruction of an ectopic ureter or ureterocele may induce reflux in either or both poles of the involved kidney. In other instances, the same action may cause existing lower pole reflux to resolve. Several means of achieving these goals are available.

For an ectopic ureter, this can mean common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis. For a ureterocele, this can be accomplished by TUI as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy. In both cases, acute decompression may be necessary owing to sepsis and the age of the child. For the ectopic ureter, acute decompression is best achieved with an end ureterostomy near the bladder, whereas for a ureterocele, TUI is usually effective.

The decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving. The presence of VUR into either of the ureters must be considered as well, and every effort should be made to correct this with the drainage procedure.

Ectopic ureters and ureteroceles are overwhelmingly dealt with postnatally. Although one might reason that a prenatal diagnosis could lead to earlier relief of obstruction and presumably a greater chance of recovery of upper pole function, the evidence in the literature seems to show that there is a limited recovery of function, even with early decompression. The observations by Tank using early endoscopic puncture demonstrated function that had not been detected before drainage (Tank, 1986). Impaired function of the upper pole occurs equally in those diagnosed prenatally and postnatally (Upadhyay et al, 2002). In most instances, the upper pole contributes little to overall renal function, but as discussed earlier, there are no criteria for what should be normal upper pole function.

KEY POINTS: CLINICAL MANAGEMENT—GOALS OF TREATMENT

- The goals of therapy are preservation of renal function; elimination of infection, obstruction, and reflux; and maintenance of urinary continence.
- Minimization of overall procedural morbidity is also a goal of treatment.
- For both ectopic ureter and ureterocele associated with a duplicated system, a primary concern is the preservation of functional renal parenchyma.
- Decision making for renal parenchymal preservation is largely empirical, and there are few objective criteria to indicate how much residual function is worth preserving.
- For an ectopic ureter, this can mean common sheath reimplantation or ureteroureterostomy, either low or proximal near the renal pelvis.
- For a ureterocele, this can be accomplished by TUI, as well as ureterocele excision and common sheath reimplantation or ureteroureterostomy.
- Observational management of ureteroceles in carefully selected patients is a reasonable option, with the potential for spontaneous decompression.

Historical Perspective

Initial management for ureterocele and ectopic ureter focused on the same goals as today, and ureterocele excision using open surgery was described in the early 1950s (Gross and Clatworthy, 1950; Campbell, 1951). Total reconstruction was presented as a viable option in the mid 1950s and again became popular in the 1970s with the reports of Hendren and Perlmuter (Hendren and Monfort, 1971; Kroovand and Perlmuter, 1979). The upper tract approach for ureteroceles, with upper pole partial nephrectomy to decompress the ureterocele, became the standard approach in the 1980s (King et al, 1983). Endoscopic incision of the ureterocele, initially as a salvage approach in the septic child, gained widespread favor in the 1990s (Tank, 1986; Rich et al, 1990), but its use is now more selectively applied based on imaging criteria. Observational management has emerged more recently, although this remains controversial.

Ectopic ureter has been usually managed surgically in nearly all patients. An early description of the clinical presentation and management of the ectopic ureter focused on removal of the associated renal unit in patients with incontinence (Aldred and Higgins, 1951). Presentation in most cases was relatively late, and residual renal function was usually limited. Excision was commonly the best option. With prenatal detection, salvage of the affected renal moiety has become a common option, usually with an upper to lower drainage procedure in duplicated systems.

Observational Management

Coplen and Austin described a subset of patients with ureteroceles and multicystic dysplastic kidneys in the associated upper tract segment (Coplen and Austin, 2004). This group had either low-grade or no reflux and no ureteral dilation. These prenatally diagnosed patients were managed nonoperatively and had a benign clinical course. Other groups have reported nonoperative management of ureteroceles meeting criteria of no obstruction of the ipsilateral lower pole or contralateral kidney and limited reflux to the lower pole (grade III or less) (Shankar et al, 2001; Direnna and Leonard, 2006), no function of the upper pole, or no obstruction on diuretic renography (Han et al, 2005). In these small cohorts, reflux (including grade IV) into the lower pole was seen to resolve in 50% to 100% without intervention. Clearly some children will do well for a period of time without intervention, and in some patients resolution of upper pole dilation and lower pole reflux has been reported. It is challenging to know how to counsel families regarding this approach, as the potential for later, unpredictable acute presentation is real. For that individual, even if with a low statistical incidence, it is very significant clinically. The long-term risk and relative balance of morbidities of this strategy and the robustness of clinical predictors have yet to be determined. Carefully considered, observational management of children with ureteroceles can be an appropriate strategy with careful selection and parental education.

Total Reconstruction

Total reconstruction of both upper and lower tracts has been advocated by some authors as being the most definitive procedure for ureteroceles (Hendren and Mitchell, 1979; Kroovand and Perlmutter, 1979). **Upper pole nephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive but is an extensive operation performed with two incisions.** Although the reported success rates are good, it remains uncertain if this is appropriate in most children when long-term relief from obstruction and reflux may be achieved with one or at most two lesser procedures. No clear clinical situations have been reported to be such that two procedures are always required, and if TUI is the first procedure, it is not comparable to either an upper or lower tract procedure. The older child with a massive ureterocele and no function of an upper pole with significant lower pole reflux might be reasonably treated with upper pole nephrectomy and ureterocele excision and bladder reconstruction. At present, the partial nephrectomy would be reasonably performed laparoscopically with a lower Pfannenstiel incision for the bladder reconstruction and reimplantation. This is an unusual clinical scenario.

Upper Pole Partial Nephrectomy

Upper pole removal using a partial nephrectomy or heminephrectomy of a duplex system is typically the preferred treatment when there is clearly no function in the upper pole and if there is concern about how effective a drainage procedure may be because of massive dilation. There are numerous series advocating one or another approach with variable results dependent on factors such as degree of reflux, age, and underlying pathology, but there are no clear data to indicate that one approach is so definitively better as to be the universal choice.

The surgical methods for partial nephrectomy have been described and remain useful and similar whether being used with open surgery, conventional laparoscopy, or robotic laparoscopy. These apply to both ectopic ureters and ureteroceles in duplex systems.

Open Partial Nephrectomy or Heminephrectomy

Heminephrectomy is a standardized procedure with relatively little recent evolution (Mor et al, 1994), but several technical points deserve emphasis (Fig. 134-25). A flank approach for heminephrectomy usually offers better exposure to the upper pole vessels. The procedure may be performed through a dorsal lumbotomy approach, which is both effective and less morbid than a muscle-dividing flank incision. In older children this exposure can become less effective, however.

In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole. The kidney should be retracted gently so as not to cause any vascular injury through traction and spasm of small vessels. Transecting the upper pole ureter and placing a traction stitch on the proximal portion of this ureter affords the surgeon a good method of retraction and manipulation of the upper pole. Once at the pedicle, dissection of the ureter both below and above the vessels allows for easier, safer freeing of the ureter. The ureter is passed behind the main renal vessels. The dissection *around* the renal vessels should be done carefully to avoid damage to the lower pole. The upper pole vessels (most often two or three in number) are sequentially ligated. Demarcation of the upper pole parenchyma becomes apparent after the upper pole vessels are ligated.

During upper pole nephrectomy, atraumatic clamping of the renal pedicle can be used, enabling work in a bloodless field. Administration of an intravenous osmotic diuretic (e.g., mannitol) moments before and after clamping of the pedicle helps prevent acute tubular necrosis. Topical vasodilating agents (e.g., papaverine) should be available in case vasospasm occurs. In general, vascular control is not essential in upper pole partial nephrectomy because the polar vessels may be identified and controlled. Resection of the upper pole renal tissue can then be carried out with electrocautery or another cutting device. Stripping the capsule off the upper pole in continuity allows it to be used in the closure. Several mattress sutures incorporating a pedicle of retroperitoneal fat are used for closure.

When performing the upper pole ureterectomy, it is of utmost importance to maintain the dissection immediately on the wall of the upper pole ureter as much as possible to preserve the blood supply to the remaining lower pole ureter.

If in addition to obstruction there is concomitant reflux into the ectopic ureter, some recommend a second incision (i.e., a Gibson incision) to resect the ureter in its entirety. Care must be taken to avoid injury to the vas deferens in male patients. To prevent complications that may arise from dissection within a common sheath of two ureters (especially distally), the back wall of the upper pole ureter can be left attached to the lower pole ureter. The remainder of the upper pole ureter should be removed (Fig. 134-26). Such a maneuver prevents damage to the lower pole ureteral blood supply, which courses between both ureters. Resection is carried out to the level of the bladder, where several sutures are placed to close the upper pole ureteral hiatus.

Other surgeons are comfortable ligating the distal refluxing ureteral stump and leaving it in situ, with few subsequent problems attributed to the small volume of reflux into that stump (Cain et al, 1998; Kim et al, 2001). The refluxing, obstructed ectopic ureter raises the most concern regarding a later infection, and as much of the ureter should be removed as is possible without injury to the bladder neck.

A Penrose drain (brought through a separate stab wound or at the edge of the incision) is placed in such a fashion as to drain the renal fossa and the area of the ureteral dissection. **Postoperative evaluation is best performed with a Doppler sonogram to demonstrate normal postoperative anatomy, absence of a urinoma,**

Figure 134-25. Technique of upper pole nephrectomy. **A**, The upper pole ureter is usually dilated and tortuous and can be identified readily at the lower pole of the kidney. It is separated carefully from the lower pole ureter, divided, and used to improve access to the upper pole moiety. **B**, The upper pole ureter is passed beneath the hilar renal vessels and retracted upward. Small feeding vessels to the upper pole are individually ligated and divided. Any larger vessels that may be supplying the upper pole can be temporarily clamped to determine the extent of their distribution. The capsule of the upper pole is bluntly stripped away, exposing the often coarse and cystic parenchyma of the upper pole. This can usually be distinguished from the smooth texture of the normal lower pole. Often, an indented demarcation is seen between the two poles. **C**, While traction is applied to the lower pole ureter, the upper pole is excised with the use of electrocautery. Vascular control is achieved by temporary clamping of the lower pole vessels. This may also be accomplished by gentle finger compression of the lower pole. Individual vessels are identified and ligated during this part of the procedure. **D**, The parenchyma of the lower pole is approximated at the site of removal of the upper pole with the use of broad mattress sutures. The redundant capsule is then brought over the site of repair and sewn together with a running suture.

and normal blood flow to the lower pole. Optionally, a functional study such as a nuclear renal scan may be performed if there is concern regarding viability of the lower pole.

Laparoscopic Partial Nephrectomy

Another surgical option is laparoscopic nephrectomy or heminephrectomy. This can be done by either a transabdominal or a retroperitoneal approach, and robotic assistance is now available. Laparoscopic procedures may offer reduced morbidity with less postoperative pain, earlier return of gastrointestinal function, earlier discharge home, and presumably a quicker return to work for the parents (Jordan and Winslow, 1993; Janetschek et al, 1997; El-Ghoneimi et al, 1998; Wang et al, 2004; Lee et al, 2005; Wallis et al, 2006; Lee et al, 2009; You et al, 2009). Other advantages

include enhanced visualization and increased magnification of the operative field, improved cosmesis, and avoidance of a second incision that is often needed for the distal ureterectomy of a nephroureterectomy.

Laparoscopic heminephrectomy can be performed in very small infants, and the operative time has decreased as experience and skill have increased (El-Ghoneimi et al, 2003; Wang et al, 2004; Lee et al, 2005; Sydorak and Shaul, 2005; Piaggio et al, 2006). Newer energy devices allow for resection of the upper pole in a bloodless field (LigaSure [Valleylab, Boulder, CO]; Harmonic scalpel [Ethicon EndoSurgery, Cincinnati, OH]; Thunderbeat [Olympus, Tokyo, Japan]).

Some authors believe that cystoscopic placement of a ureteral catheter allows for easier identification of the ureter at the time of laparoscopy (Yao and Poppas, 2000).

Figure 134-26. Surgical management of the refluxing ureteral stump. A, It is difficult to completely separate the distal 2 to 3 cm of the upper pole ureter from the lower pole ureter. The ectopic ureter is excised to this point. B, The outer wall of the ectopic ureter is excised to the bladder level. C, A transfixing suture obliterates its lumen, with care being taken not to injure the orthotopic ureter.

Laparoscopic heminephroureterectomy performed transperitoneally begins similarly to the open procedure in that the pathologic ureter is grasped as a handle and dissected closely to its wall to avoid compromise of the blood supply to the normal ureter. The upper pole ureter is passed behind the vessels and used to facilitate dissection of the upper pole. The polar renal vessels are then ligated with clips or divided with electrocautery; this allows for a more discernible demarcation of the affected upper pole (Fig. 134-27A). The plane between the upper pole collecting system and the upper parenchyma of the lower pole is developed bluntly to facilitate identifying and transecting the upper pole attachments to the lower pole (Fig. 134-27B). After the polar element is removed with electrocautery, one can check for collecting system leakage with intravenous injection of methylene blue (Yao and Poppas, 2000). Janetschek and colleagues place fibrin glue and hemostatic agents on the cut surface and then cover it with Gerota fascia to aid in hemostasis (Janetschek et al, 1997). We have not used these agents but have closed the defect over a pedicle of local fatty tissue (Fig. 134-27C).

In performing a partial nephrectomy, robotic-assisted laparoscopy offers advantages over standard laparoscopy (Lee et al, 2009). The magnification is augmented and the dexterity of the robotic instruments allows for greater precision when working around the renal pedicle and controlling the upper pole vessels, in addition to the visual advantages of a three-dimensional image. Patient and

port positioning are the same as for pyeloplasty. Vascular control may be by absorbable or metal clips or even with suture ties. The latter may be preferable by reducing the risk of avulsing a clip during later dissection. The defect is usually closed with a tongue of retroperitoneal fat laid into the defect, which is then closed with two or three mattress sutures of 3-0 polydioxanone suture (PDS) or Vicryl.

Laparoendoscopic single-site surgery (LESS) nephrectomy has been described for a single-system ectopic ureter. This technique represents the newest horizon for minimally invasive surgery because only one 22-mm multitrocar port site (recessed in the umbilicus) is used to perform the entire surgical procedure (Park et al, 2009).

Outcomes

Results of upper pole removal for ectopic ureters and ureteroceles are, in general, very good. The residual stump is rarely problematic in cases of an ectopic ureter. In cases of ureteroceles in which lower pole reflux is present, resolution may be expected in up to 20% (Husmann et al, 1999), and new reflux may be seen in 15% to 50% of patients in whom no reflux was present preoperatively. The overall secondary surgery rate after primary upper pole nephrectomy for ureterocele is 40% to 50% based on the literature. The difficulty in interpreting the literature rests in variable indications for secondary surgery. In some cases, reflux was simply followed and within the short follow-up did not cause any problems, whereas in others it was felt that removal of a nonfunctioning upper pole was necessary. Neither of these approaches has been validated by long-term data.

Complications. The most significant complication related to heminephrectomy is loss of lower pole function (Mandell et al, 1980; Wallis et al, 2006; You et al, 2009). Loss of function may be a long-term issue and may not be recognized immediately. Clinical signs of fever, increasing pain, and hematuria may be evident in the first week after surgery. Development of a postoperative upper pole urinoma has been reported in up to 20% of laparoscopic and robotic cases but is rarely of clinical significance (Valla et al, 2003; You et al, 2009). Urinomas have been reported mostly in series in which there is no formal closure of the polar defect. Whether these urinomas are caused by injury to the lower pole or remnant upper pole is unclear. Urinomas, if causing no symptoms and not expanding, can be observed. Other less common problems can include inferior vena cava laceration, duodenal perforation, total nephrectomy, and peritoneal tears (if the procedure is done retroperitoneally).

KEY POINTS: UPPER POLE NEPHRECTOMY

- In an upper pole nephrectomy, the primary concern is to avoid damaging the viable lower pole.
- Postoperative evaluation is best performed with a Doppler sonogram to demonstrate normal postoperative anatomy, absence of a urinoma, and normal blood flow to the lower pole.
- Definitive cure by partial nephrectomy for ectopic ureters is usually successful, as the residual stump is rarely problematic.
- In ureteroceles in which lower pole reflux is present, resolution may be expected in up to 20%, and new reflux may be seen in 15% to 50% of those where no reflux was present preoperatively.
- Complications related to heminephrectomy include loss of lower pole function and development of a postoperative upper pole urinoma.
- Separation of the duplicated ureters during intravesical dissection should be discouraged because it can lead to injury of the common blood supply running longitudinally between the two ureters.

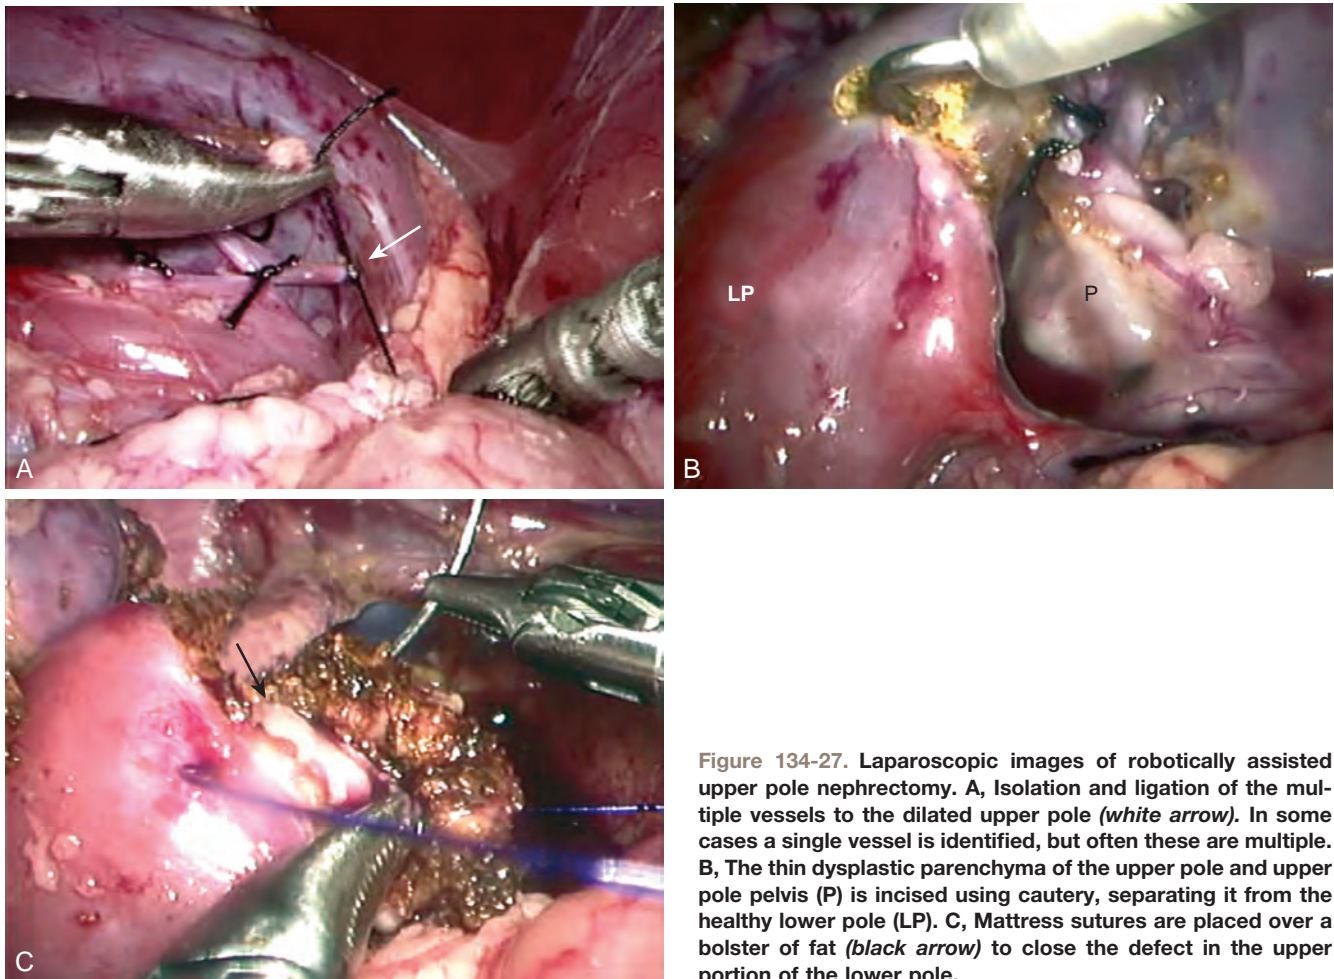

Figure 134-27. Laparoscopic images of robotically assisted upper pole nephrectomy. **A**, Isolation and ligation of the multiple vessels to the dilated upper pole (*white arrow*). In some cases a single vessel is identified, but often these are multiple. **B**, The thin dysplastic parenchyma of the upper pole and upper pole pelvis (P) is incised using cautery, separating it from the healthy lower pole (LP). **C**, Mattress sutures are placed over a bolster of fat (*black arrow*) to close the defect in the upper portion of the lower pole.

Lower Tract Reconstruction

A definitive reconstruction at the bladder is suitable for both the ectopic ureter and ureterocele. This approach has the advantage of relieving obstruction as well as correcting reflux. The disadvantages, however, are the potential for injury to the bladder neck and vagina and the complexity of the procedure. If clinically significant reflux persists after other procedures, lower tract reconstruction may be necessary.

Ureterocele Excision and Common-Sheath Reimplantation

The intravesical approach to the ureterocele begins with a transverse incision of the ureterocele between two stay sutures (Figs. 134-28A to C and 134-29A). Proximally, a plane is obtained between the ureterocele wall and the wall of the bladder. The ureterocele is dissected off the bladder to the point at which it joins the lower pole ureter. Then the two ureters are dissected as a unit, the upper pole ureter is tapered as needed, and both ureters are reimplanted submucosally. The distal portion of the ureterocele is dissected in the same plane (Figs. 134-28D and 134-29B) to the level of the bladder neck, where it is resected. The detrusor muscle is plicated if it is attenuated and it appears that it may offer insufficient backing. Bladder mucosal flaps are raised to cover the area of the removed ureterocele (Figs. 134-28E and F and 134-29C).

Once again, several technical points regarding ureterocele excision and common sheath reimplantation deserve mention. **Separation of the duplicated ureters during intravesical dissection should be discouraged, because it can lead to injury of the common blood supply running longitudinally between the two**

ureters. Plication of the detrusor muscle underlying the ureterocele may be necessary to reinforce any areas of muscle deficiency. Furthermore, the distal portion of the ureterocele may extend below the bladder neck. Extreme care must be taken in this part of the dissection to avoid injury to the sphincter mechanisms. If the entire ureterocele cannot be excised, it can be fulgurated carefully and closed over with two layers.

Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting like a windsock behind the urethra. Options include resection by gentle retraction of the ureterocele if it is not very large, closure of the opening with two layers of tissue, or fulguration of the lumen to cause collapse and closure. Careful postoperative assessment is needed in any case to identify what can be progressive voiding dysfunction if the remnant cecoureterocele creates obstructive voiding (Fig. 134-30).

An alternative approach to ureterocele resection is marsupialization, in which the thin intravesical aspect is removed and the edge is sutured. No attempt is made to reinforce the back wall, based on the empirical observation that this is not always needed. Reported results have been satisfactory (Scherz et al, 1989; Lewis et al, 2008). Although this eliminates the need to dissect out the ureterocele and avoids injury to the underlying vagina, it is our impression that this approach has inherent risks that can be avoided by a controlled and predictable surgical approach of trigonal reconstruction. A major problem with marsupialization may be uncommon, but it seems preferable to definitively correct the anatomic and functional defect as certainly as possible on the first open operation when needed.

Figure 134-28. Technique for excision of ectopic ureterocele and common sheath reimplantation of upper and lower pole ureters. **A**, Appearance of right-sided ureterocele with open bladder, viewed from below. Note proximity of the contralateral ureteral orifice. *Inset*, Cutaway side view demonstrating the close association of the two polar ureters with a common vascular supply. The *dotted line* indicates the planned initial incision of the ureterocele. **B**, After stay sutures are placed, the ureterocele is incised with electrocautery in a transverse direction, exposing the inner cavity of the ureterocele. **C**, The posterior mucosal wall of the ureterocele is incised transversely, revealing the often thinned posterior muscular wall of the bladder. This incision will then be continued around the bladder mucosal edge of the ureterocele including the orifice of the lower pole ureter. Stay sutures are important to provide adequate exposure. **D**, The upper and lower pole ureters have been mobilized and are retracted into the bladder. The distal aspect of the ureterocele is being mobilized in a similar fashion. The bladder mucosal surface will also be incised around the edge of the ureterocele to permit complete removal of the ureterocele. *Inset*, The fully mobilized distal ureterocele is retracted caudally, revealing its narrowing attachment at the bladder neck. **E**, The dilated upper pole ureter associated with the ureterocele has been tapered and remains in continuity with the lower pole ureter. Both have been brought into the bladder through a newly formed muscular hiatus to provide adequate tunnel length for the ureteral reimplantation. The thinned-out posterior bladder wall has been repaired with multiple interrupted sutures to provide adequate muscular backing for the ureters. The bladder mucosa surrounding the ureterocele defect has been mobilized to permit covering of the ureters. **F**, *Left*, The ureters have been reimplanted into the new ureteral tunnel, have been sutured distally after spatulation, and are being covered with bladder mucosa. The lower pole orifice is medial. *Right*, Final appearance of the ureteral tunnel after completion of the reimplantation.

Figure 134-29. Operative view of ureterocele excision and common sheath reimplantation. **A**, View of the decompressed ureterocele (*yellow ellipse*) after incision (*white arrow* marks site of incision and the bladder neck orifice) and marking of extent of the ureterocele and the lower pole orifice (*black arrowhead*). The contralateral duplicated ureteral orifices are indicated by the *black arrows*. **B**, The ureterocele has been divided and the lower aspect is visible (*white arrow*), going to the bladder neck. This will be excised and the trigonal floor imbricated. The two ureters have been mobilized and are seen being retracted cephalad (*black arrow*). **C**, Completed appearance of the reimplanted two ureters (*arrows*).

Figure 134-30. Voiding cystourethrogram appearance of a large cecoureterocele (UC) extending down the urethra and causing bladder outlet obstruction with voiding. The ureterocele fills, acting like an obstructive windsock. The lumen of the urethra is marked with the arrow.

Reported results of ureterocele excision and common sheath reimplantation are very good, although persisting reflux can be an issue in 5% to 10% of patients. This may be more common when ureteral tapering is needed. Whereas in some reports it is claimed that these patients do not require surgery, persisting reflux in this context must be viewed with caution.

KEY POINTS: URETEROCELE EXCISION AND REIMPLANTATION

- Cecoureteroceles present a unique challenge in ureterocele excision and reimplantation in that the distal aspect of the ureterocele can create an obstructive flap-valve with voiding, acting like a windsock behind the urethra.
- An alternative approach to ureterocele resection is marsupialization, in which the thin intravesical aspect is removed and the edge is sutured.
- The results of ureterocele excision and common sheath reimplantation are very good, although persisting reflux can be an issue in 5% to 10% of patients.
- Total reconstruction including upper pole nephrectomy with ureterocele excision and reimplantation of the lower pole ureter is definitive but is an extensive operation performed with two incisions.

Pyeloureterostomy and Ureteroureterostomy

When the upper pole of either an ectopic ureter or ureterocele is to be maintained owing to function or surgeon preference, pyeloureterostomy or ureteroureterostomy may be carried out. Both proximal and distal approaches may be used, and these have been described with open and laparoscopic techniques.

Open Procedure

Ureteroureterostomy can be performed distally to create an anastomosis between the upper pole ureter and the lower pole ureter in an end-to-side fashion. This can be done at the distal ureter via an inguinal, open approach (Huisman et al, 1987; Lashley et al, 2001; Chacko et al, 2007; Prieto et al, 2009). It is critically important in this type of procedure to correctly identify the recipient lower pole ureter, and it is strongly recommended to cystoscopically place a stent into the lower pole ureter at the start of the procedure.

Other options to achieve this goal are the proximal anastomotic technique of ureteroureterostomy or pyeloureterostomy. This results in the upper pole system's draining into the lower pole system. Such high anastomoses may be preferable to a distal ureteroureterostomy with a dilated upper pole, because the latter may result in more urinary stasis with a distal anastomosis. Whether the "yo-yo" phenomenon is clinically significant remains uncertain, but we prefer a proximal anastomosis when there is a significant mismatch in ureteral size.

When performing upper tract anastomoses, dissection should be limited to an absolute minimum, especially medially, to prevent disruption of either ureter's blood supply. The upper pole ureter may be considerably larger than the lower pole ureter. A generous longitudinal pyelotomy or ureterotomy is made in the lower recipient pole to overcome such disproportion, and the anastomosis is performed in an end-to-side fashion. The distal portion of the upper pole ureter should be aspirated with a feeding tube to decompress it. The distal upper pole ureter is resected as far inferiorly as possible, with care taken to stay directly on this ureter's wall and avoid the vasculature of the adjacent lower pole ureter. If there is no reflux, the resection is taken as distally as possible and the remnant lower portion of ureter may be left open. If reflux is present in an ectopic ureter, it should be taken as close to the bladder neck as possible. If associated with a ureterocele, it may be possible to avoid resection of the ureterocele as long as it is well decompressed.

Laparoscopic Procedure

Both ureteroureterostomy and pyeloureterostomy can be readily performed laparoscopically (Gonzalez and Piaggio, 2007; Steyaert et al, 2009), which is aided with robotic control (Kutikov et al, 2007; Smith et al, 2009). A stent is placed in the recipient ureter only and not across the anastomosis (Fig. 134-31).

Transurethral Incision for Ureterocele

The simplest means to decompress the obstructed upper pole or single system ureterocele is TUI. Reported rates of relief of obstruction range from 78% to 97% (Rich et al, 1990; Jayanthi and Koff, 1999; Di Renzo et al, 2010; Adorisio et al, 2011; Palmer et al, 2011; Castagnetti et al, 2013). A comparison between TUI and multiple punctures (watering can technique) showed no difference in decompression rates, although multiple punctures induced less reflux into the affected ureter. In the setting of acute sepsis, TUI is the most appropriate intervention, although a percutaneous nephrostomy would be a viable option as well.

Although TUI can reliably relieve obstruction, it carries the risk of inducing reflux into the affected ureter, which may then cause upper tract infection and the need for reconstruction. The balance between the minimal morbidity of TUI and its uncertainty is the basis for the clinical controversy as to its usefulness.

Our preferred method of incising the ureterocele is similar to the one described by Rich and colleagues (1990): a transverse incision through the full thickness of the ureterocele wall using the cutting current. Making the incision as distally on the ureterocele and as close to the bladder floor as possible lessens the chance of postoperative reflux into the ureterocele. One can use either a Bugbee electrode or an angled-tip wire. We favor the latter instrument because it has a finer tip and allows for more precision and the angle allows for easier manipulation. In older children, the

resectoscope with the Collins hot knife may be used to make the incision. Laser incision has been reported with equivalent results (Marr and Skoog, 2002; Jankowski and Palmer, 2006). Cold knife incision has been used as well.

The ureterocele should be incised deeply because ureteroceles may be thick walled. Adequacy of ureterocele incision is confirmed either by the escape of a jet of urine from the ureterocele or by viewing the urothelium on the inside of the ureterocele (Fig. 134-32). For the ectopic ureterocele that extends into the urethra, adequate drainage may be achieved by either a longitudinal incision that extends down from the intravesical portion into the urethral portion or two separate punctures, one in the intravesical portion

of the ureterocele and one in the urethral portion of the ureterocele.

No bladder catheter is left in place, and most children are treated as outpatients. A follow-up ultrasound is performed in 4 to 6 weeks to assess the degree of decompression (Fig. 134-33). A voiding cystogram is performed in 2 to 3 months to determine the status of lower pole reflux and whether new reflux has been created into the ureterocele (Fig. 134-34).

Figure 134-31. Operative view of robotic ureteroureterostomy for ectopic ureter presenting with incontinence. The procedure is being performed at the level of the iliac vessels. The arrow indicates the ureteral stent in the recipient (lower pole) ureter.

Figure 134-32. Endoscopic image of a ureterocele about to be incised with a hook cautery. The incision should be made inferiorly and medially to limit the risk of reflux, but the key goal is decompression. The ureterocele should be incised with the bladder partially filled, but not so much as to efface the ureterocele.

Figure 134-33. Chart indicating incidence of secondary surgery after either transurethral incision (TUI) or upper tract approach (partial nephrectomy or ureteroureterostomy) based on data from multiple sources. The number of patients (pts) is indicated adjacent to the data points. Statistical differences are indicated between selected groups based on two-tailed Fisher exact. CI, confidence interval; LP, lower pole; VUR, vesicoureteral reflux.

Figure 134-34. Appearance of the decompressed upper pole (arrow) from Figure 134-10, following endoscopic incision of the ureterocele.

The reported incidence of new reflux ranges from 0% to 50%. The risk of reflux may be dependent on the method used for incision (Tank, 1986; Rich et al, 1990; Blyth et al, 1993; Jelloul et al, 1997; Dahm and King, 1998; Husmann et al, 1999; Jayanthi and Koff, 1999; Shekarriz et al, 1999; Cooper et al, 2000; Singh and Smith, 2001; Upadhyay et al, 2002; Chertin et al, 2007). Some authors favor puncture instead of incision, but no data are available that demonstrate a clear difference. The type of ureterocele is a clear determinant of the outcomes of TUI, with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision. Decompression with no reflux can be achieved in 70% to 80% of patients. Extravesical ureteroceles, however, are more likely to have persisting or new reflux and may require secondary surgery based on the presence of reflux in 70% by some series. In the meta-analysis by Byun and Merguerian, the presence of lower pole reflux and the location of the ureterocele are similar in their impact on outcomes (Byun and Merguerian, 2006). In this analysis, the relative risk of reoperation was 1.74 times greater in the presence of reflux than without, and 2.78-fold times higher if extravesical. These factors did not seem to be additive, suggesting they represented similar underlying causes. In comparison with an open approach of any modality, however, the simplicity of ureterocele incision coupled with the potential for definitive cure, even if not in a large fraction, is appealing. TUI also acts to better prepare the patient for a secondary major surgery if needed, by decompressing dilated ureters.

Reflux Outcomes after Transurethral Incision

The natural history of lower pole reflux after TUI is incompletely defined. In some series an observational approach has been taken, and resolution has been reported in a few series with variable follow-up (Jesus et al, 2011). The usefulness of observing these patients will be dependent on occurrence of infection as well as parental preferences.

Ureterostomy for Ectopic Ureter

The ectopic ureter in a neonate with sepsis or with massive dilation may be best managed with a temporary end ureterostomy

KEY POINTS: TRANSURETHRAL INCISION OF URETEROCELE AND DRAINAGE PROCEDURES

- The reported incidence of new reflux after TUI of a ureterocele ranges from 0% to 60% and may be dependent on the method used for incision.
- The type of ureterocele is a clear determinant of the outcomes of TUI, with intravesical ureteroceles having the highest likelihood of achieving all therapeutic goals with only the incision.
- TUI also acts to better prepare the patient for a secondary major surgery, if needed, by decompressing dilated ureters.
- Persisting reflux into the upper or lower poles is typically an indication for ureterocele excision and reimplantation, but resolution has been reported.
- In general, it has not been possible to predict with any accuracy how an individual might respond to TUI based on clinical parameters.
- The ectopic ureter in a neonate with sepsis or with massive dilation may be best managed with a temporary end ureterostomy.
- Ureteroureterostomy can be performed distally or proximally to create an anastomosis between the upper pole ureter and the lower pole ureter in an end-to-side fashion.

(el Ghoneimi et al, 1996). This has the advantage of permitting acute decompression to manage sepsis and permit later assessment of any function in the affected renal unit before definitive management. By performing an end ureterostomy, the ureter can decompress and it is in position to be reimplanted if the renal unit is felt to be salvageable. No resection of redundant ureter is performed because this will shorten in time and some length will be needed to perform the reimplantation. The stoma should be positioned at what would be the lateral end of a Pfannenstiel incision. Percutaneous ureterostomy has been reported as well (Bilen et al, 2006). Assessment of functional status is performed shortly before definitive surgery, usually in 4 months or after age 6 months. DMSA scanning is probably the most efficient means, but differential urine collection is an option as well. If there is no function appreciable, partial or total nephrectomy is performed with removal of the entire ureter to the stoma.

Summary of Clinical Decision Making

For ectopic ureters, clinical decision making is much more straightforward than for ureteroceles and rests on whether to maintain the upper pole of a duplex system. If this is chosen, then the surgical approach depends on the presence of reflux in the lower pole; if present, a common sheath reimplantation or a lower pole reimplantation with distal upper to lower pole ureteroureterostomy is performed. If there is no lower pole reflux, either proximal or distal ureteroureterostomy is performed. If the degree of function is ambiguous, a temporary end ureterostomy can be used to permit assessment out of the acute setting, particularly with a massively dilated ureter. Also, if reflux is present, the need for lower surgery to correct the reflux may influence the choice to avoid upper tract surgery. If removal of the upper pole is chosen based on degree of dilation or the preference for removal of nonfunctioning, dysplastic tissue, an upper pole nephrectomy is performed. For the single-system ectopic ureter, preservation or removal is also based on degree of function and surgeon preference. There are no objective outcome data to advocate clearly for one or another approach.

For a ureterocele in a duplex system, the availability of endoscopic incision creates more options (Table 134-1 and Fig. 134-35). It is important to recognize that although TUI is an operation, it is of a totally different nature than either an upper pole nephrectomy or a lower tract reconstruction. It is inappropriate to equate them as operations in a comparative manner. In general, it has not been possible to predict with any accuracy how an individual might

TABLE 134-1 Options for Ureterocele Management

PROCEDURE	IDEAL INDICATIONS	ADVANTAGES	LIMITATIONS
Transurethral incision	Infant Large ureterocele with VUR	Outpatient procedure Effective decompression Occasionally definitive	May produce reflux into ureterocele segment, necessitating bladder surgery
Upper pole nephrectomy	Older patient Large nonfunctioning upper pole No VUR	May be definitive Removes pathology Avoids bladder level surgery	May not be definitive Significant surgery Risk to lower pole May still require lower surgery in bladder
Ureteroureterostomy or ureteropyelostomy	Older patient Functioning upper pole No VUR	Drains obstructed segment with little risk of obstruction or UTI	Leaves ureterocele in bladder May develop reflux
Ureterocele excision and common sheath reimplantation	Reflux Functioning upper pole without significant dilation	Eliminates obstruction and reflux, removes ureterocele No renal risk	Complex surgery Risk to vagina and bladder neck May require ureteral tapering

UTI, urinary tract infection; VUR, vesicoureteral reflux.

Figure 134-35. Voiding cystourethrogram demonstrating reflux into the upper pole of a duplex system after ureterocele incision. This type of reflux will rarely resolve spontaneously. Although the clinical risk is uncertain, the reflux is most often repaired.

respond to TUI based on clinical parameters. Because in some patients significant lower pole reflux and upper tract dilation may be treated with a brief outpatient procedure with documented long-term results, it would seem reasonable to offer that option before moving directly to a more complex upper or lower tract reconstruction. Even if half of those patients may need subsequent surgery, it can be safely deferred until the child is older. There is also the further appeal of TUI in that it may make a subsequent surgical procedure less complex by decompressing a dilated upper pole ureter. Reimplantation may be much more effective and not require excisional tapering. This lessens overall morbidity, another goal of management. The appeal of TUI may therefore be less in the older child with a massive upper pole in whom removal may be preferable and definitive surgery can be performed at diagnosis.

Voiding Dysfunction after Ureterocele Repair

Voiding dysfunction after lower urinary tract reconstruction for ureterocele has been reported in some series (Abrahamsson et al, 1998; Sherman et al, 2003; Lewis et al, 2008), but with a low incidence. In other series there was no evidence of incontinence or significant bladder dysfunction (de Jong et al, 2000; Vereecken and Proesmans, 2000; Beganovic et al, 2007). Abrahamsson and colleagues reported infrequent voiding with the possibility of infection in 19 of 36 patients, whereas 3 of 36 demonstrated incontinence (Abrahamsson et al, 1998). A similar observation was made with a lower incidence by Vereecken after complex bladder surgery for duplication anomalies (Vereecken and Proesmans, 2000). Abrahamsson suggested that the bladder dysfunction was the result of an intrinsic bladder abnormality rather than the surgical procedures.

In the child with either recurrent infections or incontinence after surgical repair of a ureterocele, one must consider the type of surgery and if there was the possibility of inadequate trigonal support. This can lead to a weak bladder base, ballooning of the trigone posterior to the bladder neck, and an obstructive process. This can also occur after transurethral incision of a ureterocele with a urethral component. Inadequate bladder emptying and infection as well as upper tract dilation can result.

A VCUG may be needed to assess the bladder anatomy with voiding, and video-urodynamics may be needed. It would be important to recognize the need for lateral views during voiding to identify the bladder pathology. We have also used antegrade cystoscopy via a suprapubic puncture to better assess the bladder neck. Recurrent VUR may occur, particular if there is obstructed voiding, and may require repeat VCUGs in the setting of febrile UTIs.

Managing bladder dysfunction after ureterocele repair will depend on the cause and may include bladder and trigonal reconstruction or bladder neck repair, intermittent catheterization, or, if there is evidence of bladder neck incompetence, endoscopic injection of bulking agents.

OTHER URETERAL ANOMALIES

Anomalies of Number

Bifid Ureters

Ureteral duplication may be associated with ectopia or a ureterocele but is also compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication. Ureteral duplication is a common condition, described in

approximately 1 in 125 people (0.8%) based on autopsy series, which tend to be less selective (Nation, 1944; Kaplan and Elkin, 1968; Timothy et al, 1971; Privett et al, 1976). There is a slightly higher incidence in females, estimated to be approximately 1.6:1. Duplication is unilateral six times more frequently than bilateral; however, it is clinically prudent to carefully look for contralateral duplication when unilateral duplication is documented. This may be critical in the setting of nonhydronephrotic upper poles and ureteral ectopy causing incontinence. Right and left sides appear to be affected similarly with unilateral duplication.

A bifid renal pelvis includes only a single ureter, but with confluence of the upper and lower ureters lower than the ureteropelvic junction (UPJ) constitutes partial duplication of the ureter or bifid ureter.

An increased incidence of ureterorenal pathology has been documented with duplication anomalies. The clinical implication of duplication depends largely on the ureteral insertion. A useful clinical approach is to consider that conditions that routinely affect the single-system kidney are those that affect the lower pole, including UPJO and VUR. The upper pole is more likely affected by conditions resulting from abnormal ureteral formation, including ectopic and ureterocele as previously discussed.

Lower pole UPJO evaluation and management are similar to those for a single-system UPJ obstruction. Lower pole UPJO may be identified with partial and complete ureteral duplication. Recognition of the presence of the duplication may be challenging with massive hydronephrosis, but in most cases the normal upper pole will be identified on functional imaging such as a renal scan, even if not detected on ultrasound. Lower pole UPJ obstruction may resolve spontaneously, just as a single system with comparable severity of dilation. Repair may be optionally accomplished with a pyeloureterostomy of the dilated renal pelvis of the lower pole to the normal upper pole ureter.

Upper pole UPJ obstruction has been reported, including in association with lower pole UPJ obstruction, but is exceptionally rare (Ho et al, 1995; Ng, 1999).

Hydronephrosis of the lower pole moiety may also represent VUR, and this is often of high grade. The presence of a dilated ureter on ultrasonographic evaluation will usually be present. This rarely represents ureterovesical obstruction and more often indicates VUR. Lower pole VUR is often associated with significant functional reduction in the lower pole, which is usually congenital but may also be associated with prior infection. Evaluation and management are similar to reflux into a single system, but spontaneous resolution may be more delayed (Afshar et al, 2005). Common sheath ureteral reimplantation and endoscopic injection are surgical options, as well as low ureteroureterostomy of the refluxing lower pole ureter to the upper pole ureter.

TriPLICATION

TriPLICATION of the ureter, either complete or partial, is very rare. These conditions typically have manifested with infection or wetting. The classification by Smith remains useful, in which triplex ureters are divided into four types (Smith, 1946). Type 1 constitutes three entirely separate ureters with unique attachment to the bladder or distally and accounts for 35% of triPLICATIONs. Type 2 is an incomplete separation with two ureteral orifices, occurring in 21%. Type 3 is a trifid ureter with a single ureteral orifice, seen in 31%. Type 4 describes two ureters with three orifices. This occurs with an inverted-Y bifurcation, similar to that described for duplicated ureters. The positioning of the ureteral orifices typically follows the Weigert-Meyer law (Zaontz and Maizels, 1985).

The ureters may be associated with ureteroceles (Park, 2008) and may be ectopic to the bladder neck, urethra, or vagina (Engelstein et al, 1996; Patel et al, 2001). Lower pole and mid-pole (Sivrikaya et al, 2007) UPJ obstruction may be present, as well as ureterovesical obstruction (Merlini, 1983). VUR is also described (Ander et al, 1997), as well as contralateral duplication (Srivastava et al, 1996). Fusion anomalies may be present in some (Pode et al, 1983; Golomb and Ehrlich, 1989).

Quadruple Ureters

Even more rare is ureteral quadruplication, with only eight cases reported. Most have been in adults, but three recent cases included four ureters draining into a large ureteral cyst and connecting to the bladder through a single ureter (Klinge et al, 2001; Vicentini et al, 2007; Koszutski et al, 2008). One report of a young adult with incontinence describes three of the four ureters merging and entering the bladder orthotopically, and the fourth ureter drained to the perineum. This ectopic ureter was associated with the lower mid-calyx, contrary to what the Weigert-Meyer law would predict.

Fibroepithelial Polyps

Polyps of the ureter may manifest clinically with flank pain or hematuria or by incidental detection of hydronephrosis. The most common site of attachment is at the UPJ, although they may originate from any part of the ureter. As a cause of UPJO, they are very uncommon, reported as 0.5% of all UPJ patients undergoing pyeloplasty (Adey et al, 2003; Kojima et al, 2011). A very large majority of patients were male (89%) and a majority of polyps occurred on the left side (78%). They are uncommonly bilateral, but this has been reported with clinical effects on both kidneys (Bartone et al, 1990; Lavelle et al, 1997; Bhalla et al, 2002; Adey et al, 2003; Romesburg et al, 2009). In a recent series, two of nine patients had bilateral clinically obstructive UPJ polyps. They may also be multiple. We have seen one case in which the polyp protruded from the urethra and produced severe voiding symptoms and was ultimately found to originate from the proximal third of the ureter.

Smaller polyps may not be evident on modern imaging and in a recent series were detected in 22% of patients before surgery for UPJO (Adey et al, 2003). Ultrasound may be useful in detecting these polyps (Wang et al, 2012). They would usually be seen on intravenous pyelography but may be mistaken for ureteral blood clots, particularly in the setting of hematuria (Fig. 134-36). Filling

Figure 134-36. Retrograde ureterogram of adolescent with a history of hematuria, dysuria, and a fleshy mass protruding from her urethra. The distal segment had been resected by an outside physician. The long-filling defects are typical of fibroepithelial polyps but may be confused for blood clots.

defects on retrograde pyelography in anticipation of a pyeloplasty should trigger a search for the polyps. It is unlikely that this would alter the surgical approach unless the polyp was significantly distal to the UPJ.

The cause of fibroepithelial polyps is unclear, although progressive traction resulting from ureteral peristalsis may promote edema and growth. We have seen one in which the ureter was being intussuscepted into itself owing to traction on the polyp in the mid-ureter. Histologically, they are considered benign neoplasms with fibroepithelial and vascular elements, with overlying normal to hypertrophied urothelium. There is usually a fibrovascular core with significant stromal edema. Little inflammation is seen.

Management of the polyp is dictated by the presentation and location. For polyps at the UPJ, most have undergone pyeloplasty, although the question of whether simple endoscopic resection might suffice is not settled, as there are too few cases. Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ, based on combined adult and pediatric reports (Minevich et al, 2005; Childs et al, 2009; Iwatsuki et al, 2010). Earlier reports advocated sleeve resection and reanastomosis of the ureter to prevent recurrence, yet the persisting success with ureteroscopic resection would suggest that to be unnecessary. Even earlier reports recommended nephrectomy, which cannot be justified.

KEY POINTS: OTHER URETERAL ANOMALIES

- Ureteral duplication is compatible with a normally functioning renal system if both ureters enter orthotopically or if there is partial duplication.
- It is clinically prudent to look for contralateral duplication when unilateral duplication is documented.
- An increased incidence of ureterorenal pathology has been documented with duplication anomalies.
- Conditions routinely affecting a single system kidney are those that affect the lower pole, including UPJO and VUR; the upper pole is more likely affected by conditions resulting from abnormal ureteral formation, including ectopia and ureterocele.
- Polyps of the ureter may manifest clinically with flank pain or hematuria or by incidental detection of hydronephrosis.
- The most common site of attachment of a fibroepithelial polyp is at the UPJ, although they may originate from any part of the ureter.
- UPJ polyps are best treated with pyeloplasty, although the question of whether endoscopic resection might suffice is not settled.
- Ureteroscopic removal of ureteral polyps is the recommended therapy away from the UPJ.

Anomalies of Position

Vascular Anomalies Involving the Ureter

A variety of vascular lesions can cause ureteral obstruction. With these lesions, the vascular system rather than the urinary system is anomalous. With the exception of accessory renal blood vessels, all of these lesions are relatively uncommon, although all have clinical relevance.

Preureteral Vena Cava

Anatomy. Preureteral vena cava is commonly known to urologists as *circumcaval* or *retrocaval* ureter, terms that are anatomically descriptive but misleading with regard to development (Lerman et al, 1956; Dreyfuss, 1959). The term *preureteral vena cava* emphasizes that the circumcaval ureter results from altered vascular, rather than ureteral, development. This is the more accurate term.

This disorder involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding

about and crossing in front of it from a medial to a lateral direction, to resume a normal course, distally, to the bladder. The renal pelvis and upper ureter are typically elongated and dilated in a J or fishhook shape before passing behind the vena cava. The collecting system is not inevitably obstructed. Circumcaval ureters can be classified into two clinical types (Bateson and Atkinson, 1969; Kenawi and Williams, 1976). The more common type I has hydronephrosis and a typically obstructed pattern demonstrating some degree of fishhook-shaped deformity of the ureter to the level of the obstruction. Type II has a lesser degree of hydronephrosis or none at all. Here, the upper ureter is not kinked but passes behind the vena cava at a higher level, with the renal pelvis and upper ureter lying almost horizontal before encircling the vena cava in a smooth curve. In type I, the obstruction appears to occur at the edge of the iliopsoas muscle, at which point the ureter deviates cephalad before passing behind the vena cava.

Embryology. The definitive inferior vena cava develops on the right side from a plexus of fetal veins (Fig. 134-37). Initially, the venous retroperitoneal pathways consist of symmetrically placed vessels, both central and dorsal. The posterior cardinal and supracardinal veins lie dorsally, and the subcardinal veins lie ventrally. These channels, with their anastomoses, form a collar on each side through which the ascending kidneys pass. Normally the left supracardinal veins and the lumbar portion of the right posterior cardinal vein atrophy. The subcardinal veins become the internal spermatic veins. The definitive right-sided inferior vena cava forms from the right supracardinal vein. If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.

When the definitive vena cava forms normally and the ventral portion of the primitive ring also persists, a double right vena cava is formed because of the persistence of both the right subcardinal vein dorsally and the right subcardinal vein ventrally. This double vena cava traps the right ureter between its limbs (Sasai et al, 1986).

Although bilateral vena cava or left-sided vena cava can occur (Clements et al, 1978; Mayo et al, 1983), a bilateral circumcaval ureter has been described in a case of situs inversus (Brooks, 1962). In cases of bilateral vena cava associated with a circumcaval ureter, the circumcaval ureter has been reported only on the right side, denoting that the right vena cava developed abnormally from a persistent subcardinal vein, whereas the left vena cava developed from the left supracardinal vein but otherwise normally (Pick and Anson, 1940).

Incidence. The incidence of preureteral vena cava at autopsy is about 1 in 1500 (Heslin and Mamonas, 1951), and the anomaly is three to four times more common in male than in female cadavers, although a literature review reported a ratio of 114:41 male to females (2.8:1) (Kenawi and Williams, 1976).

The symptoms of preureteral vena cava are those of obstruction. Although the lesion is congenital (Soundappan and Barker, 2004; Acharya et al, 2009), presentation in most patients does not occur until the third or fourth decade of life (Kenawi and Williams, 1976).

Diagnosis. Clinically, patients may have symptoms of flank or abdominal pain or infection, or the disorder may be discovered incidentally during other radiologic tests. Excretory urography often fails to visualize the portion of the ureter beyond the J hook (i.e., extending behind the vena cava), but retrograde ureteropyelography demonstrates an S curve to the point of obstruction with the retrocaval segment lying at the level of L3 or L4 (Kenawi and Williams, 1976). Cavography is no longer a necessary diagnostic test.

Ultrasound (Murphy et al, 1987) and CT or MRI also have been useful in defining the vascular malformation. CT urography may be the procedure of choice to confirm the diagnosis and avoid retrograde ureteropyelography (Sasai et al, 1986; Kellman et al, 1988). Nuclear renal furosemide scanning can categorize the anomaly as obstructed or nonobstructed (Pienkny et al, 1999). MRI can demonstrate the course of a preureteral vena cava and may be a more detailed and less invasive imaging modality when compared with CT and retrograde pyelography (Uthappa et al, 2002).

Figure 134-37. Fetal venous ring (A), normal vena cava (B), and preureteral vena cava (C). (Redrawn from Hollinshead WH. *Anatomy for surgeons*, vol 2. New York: Hoeber Medical Division of Harper and Row; 1956.)

Treatment. Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic. It is important to be mindful of the ureter's blood supply from the renal artery and aorta superiorly and the iliac vessels inferiorly. As stated earlier, the preferred approach for the obstructed ureter is ureteral division and relocation. Laparoscopic (Miyazato et al, 2002; Ramalingam and Selvarajan, 2003; Tobias-Machado et al, 2005; Fernandez-Fernandez and Pachano-Arenas, 2008) and robotic (Gundet et al, 2006; Smith et al, 2009) reconstruction of the ureter in a preureteral vena cava via both the transperitoneal and retroperitoneal approaches in children has been described.

Other Anomalies of Position

Several instances of horseshoe kidney have been reported (Cukier et al, 1969; Cendron and Reis, 1972; Heffernan et al, 1978; Taguchi et al, 1986). Anomalies include a variety of left renal anomalies, such as agenesis, hydronephrosis, malrotation, and hypoplasia (Kenawi and Williams, 1976). An obstructing branch of the right spermatic vein and a lumbar vein have mimicked circumcaval

ureteral obstruction (Dreyfuss, 1959; Psihramis, 1987), as has an anomalous tendon of the iliopsoas muscle (Guarise et al, 1989). **Preureteral Iliac Artery (Retroiliac Ureter).** A ureter coursing behind the common iliac artery is rare (Corbus et al, 1960; Seitzman and Patton, 1960; Hanna, 1972; Radhkrishnan et al, 1980). Either side can be involved; in two cases, the condition was bilateral (Hanna, 1972; Radhkrishnan et al, 1980). Obstruction occurs at the level of L5 or S1 as the ureter is compressed behind the artery. Coexisting anomalies are common (Nguyen et al, 1989), particularly valsal anomalies. (Seitzman and Patton, 1960; Radhkrishnan et al, 1980).

Like the preureteral cava, the preureteral iliac artery is considered to be of vascular origin without definitive proof. Normally, the primitive ventral root of the umbilical artery is replaced by development of a more dorsal branch between the aorta and the distal umbilical artery. Persistence of the ventral root as the dorsal root fails to form traps the ureter dorsally.

Ureteral or mesonephric duct ectopia is often present (Nguyen et al, 1989). The case of Seitzman and Patton involved an ectopic ureter that emptied, along with the ipsilateral vas deferens, via a persistent common mesonephric duct into the proximal posterior urethra (Seitzman and Patton, 1960). In the case of Radhkrishnan

and colleagues, bilateral retroiliac ureters also involved bilateral ectopic termination of the vasa deferentia into the ureters (Radhkrishnan et al, 1980). Luchtman and associates described ectopic vaginal termination of the involved ureter, with urometrocolpos from an imperforate hymen (Luchtman et al, 1980).

Taibah and coworkers reported the unusual finding of left ureteral obstruction from a retrointernal iliac artery ureter in an otherwise normal young woman (Taibah et al, 1987).

Vascular Obstruction of the Distal Ureter. Obstruction of the distal ureter from uterine, umbilical, obturator, and hypogastric vessels close to the bladder has been described (Campbell, 1936; Young and Kiser, 1965; Scultety and Varga, 1975). However, it is not always clear that vascular impressions on a dilated ureter are the cause of the obstruction. At times, these findings may be an artifact, as when a dilated ureter from an intrinsic obstruction is secondarily compressed against the adjacent vessel. Judging from the paucity of contemporary reports describing this lesion, it is likely that primary terminal ureteral obstruction by vascular lesions is a rare occurrence.

Herniation of the Ureter. Herniation of the ureter is another extremely rare condition. Dourmashkin searched the literature and tabulated a series of inguinal, scrotal, and femoral herniations of the ureter (Dourmashkin, 1937). Most of these were paraperitoneal—that is, a loop of herniated ureter extended alongside a peritoneal hernial sac. Only a minority were extraperitoneal (i.e., with no hernial sac present). In paraperitoneal ureteral hernias, the ureteral loop is always medial to the peritoneal sac. Of six scrotal hernias, four did not have peritoneal sacs. When the ureter extended into the scrotum, it was more likely to be dilated, causing upper tract obstruction.

In children, herniated ureters have manifested with hydronephrosis, associated with megaureters and with persistent hydronephrosis after posterior urethral valve ablation (Jewett and Harris, 1953; Powell and Kapila, 1985; Burgu et al, 2009).

Internal hernias of the ureter are even more exceptional. Reports have been published of a sciatic hernia containing a ureter (Oyen et al, 1987; Witney-Smith et al, 2007; Tsai et al, 2008; Hsu et al,

2010), herniation between the psoas muscle and iliac vessels (Page, 1955), and lumbar triangle herniation (Cabello et al, 2008). Ureteral herniation with obstruction has been reported as a rare complication of renal transplantation (Ingber et al, 2007).

KEY POINTS: PREURETERAL VENA CAVA (CIRCUMCAVAL URETER, RETROCAVAL URETER)

- Preureteral vena cava involves the right ureter, which typically deviates medially behind (dorsal to) the inferior vena cava, winding about and crossing in front of it from a medial to a lateral direction, to resume a normal course to the bladder.
- If the subcardinal vein in the lumbar portion fails to atrophy and becomes the primary right-sided vein, the ureter is trapped dorsal to it.
- The preureteral cava may manifest with symptoms of flank or abdominal pain or infection, or the disorder may be discovered incidentally.
- Surgical correction involves ureteral division, with relocation and ureteroureteral or ureteropelvic reanastomosis, usually with excision or bypass of the retrocaval segment, which can be aperistaltic.

Conclusions

Before 1990, nephrolithiasis was responsible for 1 in 1000 to 1 in 7600 hospital admissions annually throughout the United States (Nimkin et al, 1992). However, a dramatic increase in pediatric urolithiasis has been observed in more recent years (Srivastava and Alon, 2005), especially among adolescents without known metabolic disturbances. A large retrospective multihospital analysis of emergency department visits confirmed this observation finding an almost 90% increase in admission rate for pediatric patients with renal colic from 1999 to 2008 (Kairam et al, 2013). The highest risk group appears to be white, adolescent girls. It has been speculated that diets rich in sodium and carbohydrates may contribute to the etiology of urolithiasis in this cohort of children, but as yet no clear evidence supports any one etiologic theory. Metabolic risk factors are more likely to be identified in younger patients, such as patients with Dent disease, primary hyperoxaluria, or Lesch-Nyhan syndrome (Sas, 2011). In addition, diabetes and hypertension appear to be risk factors for the development of nephrolithiasis in children younger than 6 years old (Matlaga et al, 2010). Although obesity is a major health care issue among children and adolescents, an increased body mass index (defined as 25 to 29.9 kg/m²) does not predispose this cohort to increased risk of stone formation (Kieran et al, 2010). To date, there is no uniform strategy to manage pediatric stone disease (Clayton and Pope, 2011).

A complete metabolic blood profile and a 24-hour urine collection often are obtained when a stone is confirmed by imaging. There are no accepted standard reference ranges for 24-hour urine analyses in the stone-forming pediatric patients. Many pediatric urologists use adult standards to direct medical treatment because specific referenced ranges are not readily available or require additional complicated calculations. However, there are significant differences between the normal ranges of urine chemistries in children and adults (Battino et al, 2002; DeFoor et al, 2006). In addition, conflicting reports exist regarding the commonality of metabolic disturbances in the presence of calcium-based stones (Lande et al, 2005).

In the preliminary evaluation of pediatric stone disease, it is common to obtain 24-hour urine values for creatinine, sodium, calcium, oxalate, uric acid, and citrate. The cumbersome nature of a 24-hour urine collection often limits its accuracy in pediatric patients, and random urine spot sample ratios have been used. For example, urine calcium/urine creatinine ratios have been used with sensitivities and specificities of 90% and 84%, respectively, in the evaluation of hypercalciuria, a known risk factor for urolithiasis (Mir and Serdaroglu, 2005). However, such a test is limited to one

urinary metabolite and cannot be relied on to monitor responses to various medical treatments. Also, it is unreasonable to rely solely on urinary calcium excretion values as an indication of overall metabolic disturbances.

It has been suggested that measurement of urinary supersaturation products (calcium oxalate, urate) may help to improve identification of children at risk for stone formation. DeFoor and colleagues (2006) determined that supersaturation levels of calcium oxalate and calcium/creatinine ratios were significantly higher in children with stones compared with control subjects. However, this difference may have been reflective of differences found in urinary volumes. Lande and associates (2005) demonstrated that low urine volumes in children often negate the benefit of pursuing urine supersaturation products in a stone workup. Because of such conflicting data, clinicians are often confused about what urinary evaluation to pursue in the workup and management of pediatric stone disease.

Stone disease in pediatric patients has genetic, metabolic, dietary, and anatomic causes. There are numerous genetic causes of hypercalciuric nephrolithiasis alone that contribute to pediatric stone disease (Stechman et al, 2009). In this regard, medical treatment always accompanies endourologic management. To treat the pediatric patient with stone disease completely, there must be a focus on prevention through diet and medication monitoring. For this reason, the pediatric nephrologist is a critical player in the management and surveillance of these children. Details regarding the metabolic workup and medical treatment of pediatric stone disease are beyond the scope of this chapter; however, metabolic abnormalities are most often present, and hypocitruria is most common (Kovacevic et al, 2012). Numerous pediatric nephrology resources are available. Alon (2009) provides an excellent pediatric nephrology review including medication dosing by weight. Litholink (www.litholink.com) can provide parents and pediatric urologists with valuable information.

ENDOUROLOGIC MANAGEMENT

The management of upper urinary tract calculi has evolved dramatically in adults and children in the last two decades. Progress in the management of pediatric stone disease has been motivated by surgeon prowess of adopting and applying adult endourologic methods. The most important catalyst in the evolution of surgical advancement has been the expansion of minimally invasive surgery in general with development of smaller and more durable

endoscopic equipment. This advance has allowed easier endourologic treatment in children at an earlier age (Onal et al, 2013).

Extracorporeal shock wave lithotripsy (ESWL) transformed the management of pediatric upper tract calculus disease when it was introduced in the 1980s, and it remains very useful today. Other modalities of treatment, including ureteroscopy, percutaneous nephrolithotomy (PCNL), and combination treatment protocols allow for flexibility in management. However, a consensus has not been reached as to the most effective and safe technique for upper tract urolithiasis, especially between ESWL and ureteroscopy. Despite the lack of compelling scientific data comparing these treatment methods in children, ureteroscopy is the first-line treatment in many centers.

Pediatric stone disease has always been more prevalent in underdeveloped countries. Melamine-tainted milk has been associated with bilateral renal calculi in children 6 to 18 months old (Wen et al, 2010, 2011). The observation that pediatric stone disease is becoming more prevalent in the Western hemisphere is concerning. Many pediatric patients with urolithiasis have metabolic abnormalities (Jayanthi et al, 1999). There has been an increased demand on pediatric urologists to manage simple and complex urolithiasis in all pediatric age groups.

EVALUATION

Imaging

Radiographic assessment of a child with calculus disease must be accurate, economical, and safe. **Goals include determination of stone location, size, and density and urinary tract anatomy.** Children in whom radiographic assessment is indicated include children with a suspected calculus with acute symptoms and children with known calculus disease requiring follow-up evaluation to determine either stone burden or recurrence. Radiographic evaluation also is important in children with abnormal urinary tract anatomy that may predispose to calculus formation requiring eventual surgical management.

Radiographic imaging in children is similar to imaging in adult patients. The workup begins when the diagnosis of a calculus is suspected, and the radiographic study is determined by factors such as acuity of presentation and treating hospital practices. Many, if not most, children with renal colic present to an emergency department, and **unenanced helical computed tomography (CT) is the most accurate and efficient first choice in initial imaging.** Typically, a thin-slice helical protocol is defined by narrow collimation (≤ 5 mm). CT not only is able to visualize the entire urinary tract for the tiniest calculus, but it also potentially can rule out alternative diagnoses. Unenhanced helical CT of the abdomen and pelvis to evaluate urinary tract calculi was first described in 1995 and is the mainstay for imaging of calculi in adolescents and adults replacing more traditional studies such as intravenous pyelogram, kidney-ureter-bladder (KUB) radiograph, and ultrasound scan (Smith et al, 1995). With increased usage and familiarity with the technique, the application of unenhanced helical CT has expanded to include pediatric patients with similar advantages. These advantages include high sensitivity and specificity, ready availability, and speed in assessment; also an intravenous contrast agent is not necessary. Because children are at significant lifetime risk for recurrence of urolithiasis, judicious use of unenhanced helical CT is necessary to limit radiation exposure, particularly gonadal exposure, because of concerns of potential increased risk of future malignancy. There are ongoing efforts to monitor radiation exposure in children treated in the inpatient setting with the intention of mitigating future cancer risk. Kuhns and associates (2011) estimated the lifetime calculated cancer risk in children who underwent a single CT scan for stone disease workup to be increased to 2 in 1000 to 3 in 1000 compared with naturally occurring pediatric malignancies.

CT is highly accurate in stone assessment with greater than 96% sensitivity and specificity independent of the location of the calculus (Smith et al, 1996; Hamm et al, 2001; Heneghan et al, 2003; Palmer et al, 2005). CT also is helpful in demonstrating second-

ary signs of acute obstruction, such as hydroureteronephrosis, renal enlargement, and perinephric or periureteric stranding; however, the latter findings may be less obvious or absent in pediatric patients because of comparably less retroperitoneal fat (Smith et al, 1996; Smergel et al, 2001; Strouse et al, 2002).

Progress has been made in developing unenhanced CT protocols that minimize the radiation dosage without compromising diagnostic information (Heneghan et al, 2003; Cody et al, 2004; Singh et al, 2009). Experimental protocols using anthropomorphic pediatric phantoms have been used in numerous studies to determine specific organ doses, calculate effective dose, and determine the lifetime attributable risk for cancer incidence and relative risk of cancer induction from a single scan under standard-dose and low-dose modes (Brisse et al, 2009; Kim et al, 2010). Computer-simulated dose reduction has been useful in determining diagnostic thresholds in children. Compared with standard protocols, halving the dose to 40 mAs for children weighing 50 kg or less does not significantly affect the diagnosis of pediatric renal stones (Karmazyn et al, 2009). Spielmann and colleagues (2002) found excellent detectability of calculi measuring between 2 and 8 mm using much lower amperage with an almost threefold decreased estimated radiation dose compared with standard protocols. Perhaps most importantly, radiation exposure can be reduced effectively by reducing the number of CT examinations performed for poor clinical indications, scanning only the anatomic region of interest, and not performing both unenhanced and contrast-enhanced scanning unless absolutely necessary (Cohen, 2009).

Ultrasonography has a more limited role in assessment of urolithiasis compared with CT but has the distinct advantage of no associated ionizing radiation. Ultrasonography should be considered as a screening tool in the workup for nonemergent abdominal or flank pain. Although useful in the evaluation of renal calculi or hydronephrosis, ultrasonography is technically limited for use in diagnosis of a ureteral stone with the possible exception of the very distal ureter or bladder. Especially in the acute setting (i.e., symptomatic presentation with renal colic or hematuria), ultrasonography is less useful in detecting or directing management of urolithiasis. One group demonstrated that ultrasonography was nondiagnostic in 41% of children compared with 5% with CT and failed to detect ureteral calculi in 62% of pediatric patients (Palmer et al, 2005). Similar results were reported in adults confirming that ultrasonography is of limited value in the workup of urolithiasis (Fowler et al, 2002). Ultrasonography and a KUB radiograph alone may suffice in symptomatic children with a known history of renal urolithiasis or children on observation protocols, limiting exposure to ionizing radiation. It has been demonstrated in children and adults at high risk for nephrolithiasis that an initial ultrasound scan was not associated with significant differences in complications, serious adverse events, pain scores, return emergency department visits, or hospitalizations compared with patients undergoing an initial CT scan (Johnson et al, 2011; Smith-Bindman et al, 2014).

Fluoroscopy has an important role in the real-time detection and management of urolithiasis in children, and the same important safety concerns as with CT exist with respect to radiation exposure. C-arm fluoroscopy is used in the surgical setting to assist in antegrade percutaneous access of the upper urinary tract and retrograde access of the lower urinary tract. Manipulation of endoscopic instruments in vivo often requires fluoroscopic monitoring. Fluoroscopy also is used during ESWL to assist in stone localization and to monitor the effectiveness of treatment. Urologists must have a working understanding of the principles of fluoroscopy and be aware of the intraprocedure fluoroscopy time and energy settings to limit radiation exposure to the pediatric patient and the operative staff.

CONSERVATIVE MANAGEMENT

Conservative management of pediatric nephrolithiasis is considered first-line treatment, provided that there is no evidence of an

KEY POINTS: EVALUATION OF STONE DISEASE

- There has been a dramatic increase in the incidence of pediatric urolithiasis, especially among white, adolescent girls.
- Evaluation of pediatric stone disease must include genetic, metabolic, dietary, and anatomic causes.
- Goals of pediatric stone disease evaluation include determination of stone location, size, and density and urinary tract anatomy.
- A complete metabolic workup including a 24-hour urinalysis should include creatinine, sodium, calcium, oxalate, uric acid, and citrate measurements.
- Although unenhanced helical CT scan is the most accurate and efficient imaging study for stone disease, judicious use is necessary to limit radiation exposure; ultrasonography should be considered as a screening tool in the workup of nonemergent renal colic.

obstructing stone harboring an infection or a child is failing to thrive as a result of stone disease. Clinical scenarios including anorexia for more than 24 hours, persistent nausea and vomiting, and pain refractory to conservative measures should prompt endourologic intervention. In the case of a stone-bearing solitary kidney, early intervention is favored over conservative treatment. **In managing stone disease in pediatric patients, renal calculi smaller than 3 mm are likely to pass spontaneously, and stones 4 mm or larger in the distal ureter are likely to require endourologic treatment** (Van Savage et al, 2000). This information should be relayed to caregivers and parents. If a ureteral stent is placed acutely in children for the clinical circumstances described earlier, definitive endourologic therapy is delayed 4 to 6 weeks to allow for decompression, ureteric orifice dilation, resolution of edema, and proper treatment and clearance of any infection if necessary.

Many studies in adults have evaluated the efficacy of medical expulsive therapy to facilitate distal stone passage. Use of α antagonists, calcium channel blockers, and steroids has been shown to be effective. Based on efficacy demonstrated in adult patients (Porpiglia et al, 2004), α -receptor antagonists such as tamsulosin may be offered on an individualized basis as adjunctive therapy to facilitate ureteral expulsion in children. To date, however, published data to prove superiority of these agents over standard pain medication in pediatric patients are lacking. For example, a Turkish study demonstrated that daily administration of 0.03 mg/kg of the α antagonist doxazosin versus analgesic alone did not show superior expulsive results with regard to distal ureteral stones measuring up to 10 mm in children 2 to 14 years old (Aydogdu et al, 2009).

Pediatric Considerations

Special considerations in the endourologic management of stone disease in children include preservation of renal development and function, prevention of radiation exposure, and minimizing need for re-treatment. Despite advances in endourologic equipment and technique, controversy remains regarding the contribution of shock wave lithotripsy (SWL) to future development of diabetes or hypertension and whether ureteric orifice dilation during ureteroscopy leads to ureteral stricture formation or development of vesicoureteral reflux. International consensus is lacking as to the most effective surgical management of pediatric stone disease because of a lack of prospective randomized trials comparing treatment modalities and disparity in the access to emerging technologies. **Regardless of treatment modality, the presence of residual stone fragments (RFs) is associated with adverse clinical outcome** (Afshar et al, 2004), and every attempt should be made to achieve a stone-free status. Surgeon experience is paramount to facilitate complete stone clearance and minimize re-treatment rates. The decision regarding the most efficacious primary treatment modality must be individualized to the child based on age, anatomy, location, and composition of stone burden.

Antibiotic Use

In line with the 2008 American Urologic Association best practice statement on antibiotic prophylaxis, 24 hours or less of perioperative antibiotics is indicated in all patients undergoing upper tract instrumentation (Wolf et al, 2008). In children, appropriate agents include trimethoprim-sulfamethoxazole, first-generation and second-generation cephalosporins, and ampicillin in combination with an aminoglycoside. A urine culture is mandatory before all upper tract procedures to determine if the urine is sterile, and culture results are used to guide preoperative antibiotic therapy, particularly for patients undergoing percutaneous procedures, patients with high-grade obstruction, or patients with an indwelling stent (Wu and Docimo, 2004). In our practice, children with a negative urine culture undergoing uncomplicated SWL and ureteroscopy procedures receive perioperative cefazolin, and all children undergoing a percutaneous procedure or who have a preexisting ureteral stent or nephrostomy tube receive a fluoroquinolone or ampicillin/gentamicin. Use of postoperative antibiotics is controversial and is determined on an individual basis for each child, especially with more recent data demonstrating an increased risk of developing resistant bacterial strains with prolonged use of antibiotic prophylaxis (Conway et al, 2007).

SHOCK WAVE LITHOTRIPSY

The emergence of SWL during the early 1980s revolutionized minimally invasive treatment of adult urolithiasis. Since the initial report on successful SWL use in children in 1986 (Newman et al, 1986), large series have reported complication, safety, and stone-free rates comparable to adult cohorts (Table 135-1) (Myers et al, 1995; Elsobky et al, 2000; Ather and Noor, 2003; Muslumanoglu et al, 2003; Rizvi et al, 2003; Aksoy et al, 2004; Raza et al, 2005; Demirkesen et al, 2006). When used as a primary treatment option for upper tract calculi, SWL efficacy ranges from 68% to 84% (Myers et al, 1995; Rizvi et al, 2003; DeFoor et al, 2005). SWL has been a preferred treatment modality for uncomplicated renal and proximal calculi 15 mm or smaller in pediatric patients. In a contemporary series of 216 children (mean age of 6.6 years) with a mean stone size of 14.9 mm undergoing SWL with the Dornier HM3 lithotripter, Landau and colleagues (2009) reported a 3-month stone-free rate of 80%, demonstrating that stone-free rates can be achieved efficaciously in appropriate candidates. **Complications are minimal and range in severity from hematuria and ecchymosis to obstruction with sepsis** (Farhat and Kropp, 2007).

Although well tolerated in children, current stone-free rates with SWL are difficult to interpret from the existing body of data because of discrepancies between studies with regard to type of lithotripter, number of shocks administered, and re-treatment rates. **Data suggest that stone-free rates in children with a history of a urologic condition or urinary tract reconstruction are quite low (12.5%); with alternative surgical techniques available, such children may be better served with ureteroscopy or PCNL** (Nelson et al, 2008). Despite encouraging results, SWL has not been approved by the U.S. Food and Drug Administration for use in children, although it is a widely accepted treatment modality.

Shock Wave Lithotripsy Technique in Children

General anesthesia is administered in most smaller children to avoid patient and stone motion and the need for repeated repositioning. With modern lithotripters, intravenous sedation has been successfully employed in some older children (Aldridge et al, 2006). Bowel preparation is seldom used to avoid dehydration and electrolyte imbalance postoperatively. The number of shocks delivered and the kilovoltage used vary per lithotripter, but the current consensus is that low power settings (17 to 22 kV) be used to prevent stone migration during the procedure, with 3000 shock waves per session (<2000 in very young children) (Farhat and Kropp, 2007). A report assessed and compared the number and intensity of shock

waves required for stone fragmentation in 44 children (mean age of 5.9 years) and 562 adults (mean age of 40.9 years). With an equivalent number of sessions (1.1 vs. 1.1), the mean number of shock waves (950 vs. 1262, $P < .001$) and kilovoltage required (11.8 kV vs. 12.4 kV, $P < .001$) were significantly reduced in the pediatric cohort (Kurien et al, 2009).

Whether or not to place a ureteral stent before ESWL in children is controversial and a matter of personal preference. It is unclear if placement of a ureteral stent before SWL facilitates fragment passage and improves stone-free outcomes. Although rates of stent placement before SWL are inconsistent across series, **current relative indications include solitary kidneys, staghorn calculi, large ureteral calculi, obstruction, or abnormal anatomy and are not based on total stone burden.** Ureteral catheters with retrograde opacification are occasionally employed by some clinicians to aid in the localization of radiolucent calculi.

Stone Size, Location, Composition, and Patient Age

Although early series focused primarily on the feasibility, safety, and efficacy of SWL in children, more recent efforts have centered on identifying demographic, anatomic, and stone-related prognostic factors for treatment success. SWL is considered the primary treatment for upper tract calculi 15 mm or smaller in children (Farhat and Kropp, 2007), but evidence to support this stone size cutoff is lacking. Ather and Noor (2003) analyzed the correlation between stone size and clearance in 105 children younger than 14 years old. They reported an overall stone-free rate of 95% after a mean of 1.7 SWL treatments; 5% of patients required additional procedures as adjuncts to SWL. In this cohort, mean stone size in the treatment success group was 14 mm compared with 16 mm in the treatment failure group (Ather and Noor, 2003). In contrast, Elsobky and coworkers (2000) reported a 91% stone-free rate for mean stone diameter less than 10 mm versus 75% stone-free rate for mean stone diameter greater than 10 mm. Shouman and colleagues (2009) reported on a series of 24 children with a mean stone size of 31 mm undergoing SWL with the Dornier DoLi S device. In 53 sessions requiring a mean number of 3489 shock waves per session, stone-free and complication rates were 83.3% and 25%, respectively (Shouman et al, 2009). Although it is possible to treat very large stone burdens with SWL, concerns include the need for more shock treatments, more frequent re-treatment sessions, and increased risk of postoperative obstruction. Further study delineating a clear size cutoff for uncomplicated upper tract stone burden is required to counsel parents regarding the most effective first-line therapy for renal calculi between 1 and 1.5 cm.

Stone attenuation is an important predictor of success of stone fragmentation. McAdams and colleagues (2010) reported a stone attenuation of less than 1000 HU to be a significant predictor of SWL success in children, and El-Assmy and associates (2013) more recently reported that stone attenuation of 600 HU or less and stone length of 12 mm or less were the only significant predictors of success.

Renal anatomy and stone location has been a subject of more recent interest. The most effective management of lower pole calculi, a subject of frequent debate in adult patients, has yet to be determined in children. Stone-free rates from initial small retrospective SWL series range from 56% to 61% (Ozgur Tan et al, 2003; Onal et al, 2004) with re-treatment rates of 40% (Onal et al, 2004). SWL failure and re-treatment rates were associated with increased mean stone burden (Onal et al, 2004), increased infundibular length (Ozgur Tan et al, 2003), and infundibulopelvic angle greater than 45 degrees (Ozgur Tan et al, 2003).

Staghorn calculi are uncommon in children and represent a management challenge. Although monotherapy success rates are low in adults, acceptable stone-free rates in children have been achieved with SWL. In 23 children stratified by age with a mean stone burden of 1.6 cm, Lottmann and coworkers (2001) reported an overall stone-free rate of 82.6% with only one case of symptomatic obstruction. A ureteral stent was placed in 22% of children, and the authors reported an 88% stone-free rate in children younger

than 2 years old compared with 71% in children 6 to 11 years old (Lottmann et al, 2001). In 42 children with a mean stone burden of 3.2 cm stratified by ureteral stent placement, Al-Busaidy and colleagues (2003) reported an overall stone-free rate of 79%. Although stent placement did not affect stone-free rates, stent placement significantly reduced the major complication rate (Al-Busaidy et al, 2003). **The superior success rates with SWL monotherapy in children compared with adults have been attributed to softer stone composition, smaller relative stone volume, increased ureteral compliance to accommodate RFs, and smaller body volume to facilitate shock transmission.**

SWL safety and efficacy have been demonstrated even in very young children. McLorie and colleagues (2003) treated 34 children younger than 3.5 years old (mean age of 23 months) and reported an 86% overall stone-free rate (66% after one treatment) without major complications. Treatment of proximal ureteral stones has achieved similar success rates to renal stones in most pediatric series, although ureteral stenting is more commonly employed to aid in stone localization and clearance (Myers et al, 1995). Treatment of mid-ureteral to distal ureteral calculi historically has been avoided in children because of difficulties with localization over the sacroiliac joint and concern regarding possible injury to developing reproductive systems. The greater and lesser sciatic foramen has been explored as a potential blast path to treat distal stones in children.

SWL success by stone composition is similar between adult and pediatric patients. Cystine stones are uniquely challenging owing to their durability and high recurrence rates. Although SWL monotherapy has demonstrated variable results in adults, there are few reports in pediatric patients. In a small series, Slavkovic and associates (2002) reported a 50% stone-free rate in six children with cystine stone burden ranging from 0.2 to 2.5 cm. Although stone-free rates were low, fragmentation was achieved in 100% of patients, and stone dissolution was achieved with medical therapy in the remaining children after SWL (Slavkovic et al, 2002). Other authors have proposed that cystine stones formed within 2 years of therapy may be more easily fragmented with SWL and that stone number and not diameter may be more predictive of success (Farhat and Kropp, 2007).

Limitations and Concerns

In children, there is currently no consensus regarding the maximum size of RFs that are considered clinically significant (Wu and Docimo, 2004; Farhat and Kropp, 2007), and as a result there is no clear definition as to what constitutes "stone-free" status. Although children have been shown to have a greater capacity to clear RFs than adults (Gofrit et al, 2001), the presence of RFs has been correlated with an adverse clinical outcome (Afshar et al, 2004). Afshar and associates followed 26 renal units with RFs 5 mm or smaller and reported that although 31% were asymptomatic with no RF growth, 69% had adverse clinical outcomes, including RF growth or clinical symptoms. Patients with RFs had a significant increase in adverse clinical outcomes compared with stone-free subjects, and the presence of metabolic disorders was associated with RF growth (Afshar et al, 2004). For these reasons, metabolic evaluations are now routinely performed in children with a history of calculi, and every attempt should be made to achieve stone-free status.

Although SWL is well tolerated in children with few complications, stone-free rates after single-session monotherapy may be only 44% (Muslumanoglu et al, 2003). As a result, children are subjected to multiple treatments requiring general anesthesia (Aldridge et al, 2006). The need for multiple treatment sessions is concerning because the effects of shock waves on renal tissue are unclear. A growing body of evidence in adults indicates that shock waves result in renal vessel vasoconstriction and that renal tubular injury and subcapsular hematoma from cavitation and shear forces are dependent on the kilovoltage applied (Lingeman et al, 2003). In a large series of 340 adult patients with a mean follow-up period of 19 years after SWL, Krambeck and colleagues (2006)

reported an increased risk of hypertension and diabetes mellitus related to bilateral treatment, number of administered shocks, and treatment intensity. Although these results are concerning, differences between pediatric and adult populations and limitations inherent to a questionnaire-based retrospective study make application of these data in children difficult.

Retrospective studies with limited follow-up in children reported that SWL and PCNL do not cause renal morphologic or functional alteration as measured by glomerular filtration rate and serial dimercaptosuccinic acid functional studies (Wadhwa et al, 2007); however, long-term data to date are unavailable. To eliminate confounding variables and address fully the risks of chronic renal damage from SWL, long-term prospective data in children are required.

KEY POINTS: CONSERVATIVE MANAGEMENT AND SHOCK WAVE LITHOTRIPSY

- Calculi less than 3 mm are likely to pass spontaneously, whereas stones 4 mm or larger in the distal ureter are likely to require endourologic treatment.
- Surgical treatment should be predicated on achieving a stone-free status because the presence of RFs is associated with adverse clinical outcomes.
- Although complication rates with SWL are low, stone-free rates are difficult to interpret in children.
- SWL failure and re-treatment rates were associated with increased mean stone burden, increased infundibular length, and infundibulopelvic angle greater than 45 degrees.
- Children with urologic conditions or a history of urinary tract reconstruction may be better served with other surgical approaches because SWL stone-free rates are undesirably low.

URETEROSCOPIC MANAGEMENT OF UPPER URINARY TRACT CALCULI

The indications for primary ureteroscopic management of upper tract calculi in children have significantly expanded. In combination with new endourologic instrumentation and holmium:YAG laser, access and treatment of calculus disease throughout the entire pediatric urinary tract is effective, safe, and readily available in the acute setting. Adoption of ureteroscopy in the treatment of pediatric upper tract calculus disease lagged behind the adult experience because of concerns regarding large ureteroscope caliber size in children. However, evolving experience with ureteroscopy and more recent large, single-center retrospective series reporting comparable stone-free and complication rates of SWL in children validate the growing application of ureteroscopy in children.

Indications

Since the mid 1980s, with the acceptance of SWL as primary therapy for upper tract calculi smaller than 1.5 cm, ureteroscopy historically has been used for calculi below the iliac crests and for upper tract calculi after SWL failure (Wu and Docimo, 2004). Ureteroscopy was not considered primary therapy for upper tract stones in children because of complications from ureteral ischemia, perforation, stricture formation, and development of vesicoureteral reflux as a result of dilation of small-caliber ureteric orifices.

With significant improvements in the miniaturization and the durability of endoscopic equipment and the acceptance of the holmium laser, ureteroscopy has become a more attractive option in young children. Early series using rigid ureteroscopy for distal stones reported stone-free rates ranging from 86% to 100% with minimal complications (Table 135-2) (Ritchey et al, 1988; Van Savage et al, 2000; Schuster et al, 2002; Rizvi et al, 2003; De Dominicis et al, 2005; Minevich et al, 2005; Tan et al, 2005). Among

children randomly assigned to either ureteroscopy or SWL as primary therapy for distal ureteral stones, the children treated with ureteroscopy were reported to have a significantly higher stone-free rate after one treatment (94% vs. 43%) (De Dominicis et al, 2005). Another group reported experience using 4.5-Fr, 6-Fr, and 8-Fr rigid ureteroscopy to treat proximal ureteral stones in children with a mean age of 10.7 years. Ureteral dilation was not performed in any of the cases, and 100% of children were rendered stone-free (Lesani and Palmer, 2006). The results of these retrospective studies have helped to refute the notion that dilation of the pediatric ureter results in vesicoureteral reflux or the development of ureteral strictures. In a systematic review of the literature encompassing 221 pediatric ureteroscopies, Schuster and colleagues (2002) noted only two ureteral strictures and a low incidence of vesicoureteral reflux. Newer 4.5-Fr semirigid ureteroscopes with working ports that accommodate 2.4-Fr endosurgical instrumentation extend the versatility of managing distal ureteral calculi in most pediatric patients without predilation.

Standardization in the treatment of distal calculi in children led many centers to expand ureteroscopy to the treatment of upper tract calculi (see Table 135-2). Comparable stone-free rates approaching 100% with complication rates similar to the adult population have been reported (Minevich et al, 2005; Lesani and Palmer, 2006; Cannon et al, 2007; Corcoran et al, 2007; Smaldone et al, 2007). Smaldone and colleagues (2007) reported a 91% stone-free rate with a mean follow-up period of 10 months in a series of 100 children with a mean stone diameter of 8.3 mm, 52% of whom had upper tract calculi. Staged procedures were performed in 9% of these children. The authors reported a 4.2% perforation rate managed with ureteral stenting and one distal ureteral stricture requiring open neocystostomy (Smaldone et al, 2007). Corcoran and associates (2007) reviewed a cohort of 47 children (mean age of 9.4 years) with upper tract calculi managed with flexible ureteroscopy and holmium laser lithotripsy. An 88% stone-free rate with a mean stone burden of 10.2 mm was reported with 26% requiring staged procedures. These authors concluded that because of improved ureteroscopic access to the pediatric upper tract, calculi measuring 15 mm were as safely and effectively treated in children as in adults (Corcoran et al, 2007). Even with outstanding pediatric ureteroscopic technology, pediatric ureters may require a period of stenting before embarking on endoscopic treatment. For example, a smaller caliber ureter, resistant to instrumentation, may be passively dilated with an indwelling stent over 6 to 8 weeks (Fig. 135-1).

Adoption of techniques used in adult patients, most notably sequential coaxial and balloon dilation of the ureteric orifice and use of ureteral access sheaths, has further facilitated access to the pediatric urinary tract. Initially described in 8 children by Singh and coworkers (2006), ureteral access sheaths have been shown to facilitate repetitive upper tract access, reduce intrarenal pressures, decrease operative time, and improve stone-free rates in adults. Access for the treatment of lower pole calculi is possible with the use of ureteral access sheaths and 6.9-Fr flexible ureteroscope; this stone location previously would have required SWL or PCNL. Cannon and associates (2007) reported a 76% stone-free rate in 21 children with lower pole calculi and a mean stone diameter of 12.2 mm. After a mean of 11.4 months, no major complications were observed (Cannon et al, 2007). With the transition from SWL to ureteroscopy as a primary treatment modality at our institution, current relative contraindications to ureteroscopic management include staghorn stones in recurrent stone formers more amenable to PCNL, anatomic anomalies making retrograde access difficult, and previous endoscopic failure.

Equipment

Having an updated and well-stocked system that is familiar to the operative staff is vital to efficient management. It usually falls on the nursing staff to care for the delicate instruments and maintain them in working condition so that the instruments are operational when needed; maintenance is often needed after 20 to 30 uses. A

Figure 135-1. Computed tomography scan (A) and retrograde pyelogram (B) in a 10-year-old girl with glucose transport deficiency demonstrating a 9-mm renal pelvic stone (*arrowheads*). Nephrolithiasis was secondary to profound hypocitruria and hypercalciuria. Primary ureteroscopy could not be accomplished because of a narrowed segment of proximal ureter (*arrow*). After 8 weeks of ureteral accommodation with an indwelling stent, flexible ureteroscopy with laser lithotripsy and stone basketing was performed.

Figure 135-2. Pediatric semirigid self-dilating ureteroscopes may be used for rigid ureteroscopy in toddlers. A 4.5-Fr distal beak allows easier passage to facilitate dilation with the 6.5-Fr proximal component. (Photo provided by Richard Wolf; © Richard Wolf, all rights reserved.)

“basic” ureteroscopic kit is listed here; however, variation exists based on manufacturers. Various semirigid and flexible pediatric ureteroscopes in addition to ureteral access sheaths are available from numerous companies (Buscarini and Conlin, 2008). In general, semirigid ureteroscopes usually have a 2.4-Fr to 3.5-Fr working port, and flexible ureteroscopes have a 1.8-Fr to 3.5-Fr working port. With flexible ureteroscopes, distal tip deflection up to 270 degrees facilitates access to most lower pole stones (Figs. 135-2 and 135-3). However, smaller working areas and difficulties in exchanging instruments through the working element of a deflected ureteroscope may limit this treatment modality in some cases (Fig. 135-4).

The contents of a basic ureteroscopic kit are as follows:

Ureteroscopes:

- 6.9-Fr flexible ureteroscope
- 4.5-Fr and 6.5-Fr semirigid ureteroscope

Endourologic equipment:

- Guidewires: 0.035-inch Sensor GW, 0.018- to 0.025-inch Glidewire
- Basket devices: Zero-tip
- 8/10-Fr coaxial ureteral dilators
- Ureteral access sheaths (9.5-Fr and 11-Fr internal diameter)
- Double-J ureteral stent array: 3 Fr, 4.8 Fr, and 6 Fr

Ureteroscopic Technique in Children

All ureteroscopic procedures are performed under general anesthesia with paralysis to prevent patient movement and minimize the risk of ureteral perforation. When clinically appropriate, a sterile urine culture should be confirmed before surgery. Following broad-spectrum antibiotic prophylaxis, patients are placed in the lithotomy position, and rigid cystoscopy (7.5 Fr, 11 Fr, or 18 Fr) is performed to obtain a retrograde pyelogram and place a safety or working wire under fluoroscopic guidance. Initial ureteric orifice dilation is performed under C-arm fluoroscopic guidance with 8/10-Fr coaxial dilators in ureters that have not been stented beforehand or when the rigid/flexible ureteroscope cannot be advanced easily. We generally do not use balloon dilation of the ureteric orifice because of less control and cognitive “feel” during active dilation as well as concern for development of ureteral stricture from ischemia. If we encounter difficulty passing the 8/10-Fr dilator easily, we prefer to place a stent and return for a second procedure rather than dilate more aggressively.

The decision to use a flexible (6.9-Fr) or semirigid (7.5-Fr) ureteroscope is determined based on size and location of the stone, anatomic factors, and individual surgeon preference. Rigid or

Figure 135-3. Flexible ureterscopes offer thumb control (A) for biplanar 270-degree deflection (B). Working channels from 1.8 Fr to 3.6 Fr can accommodate working elements such as a holmium:YAG laser fiber (C). (Photos provided by Richard Wolf; © Richard Wolf, all rights reserved.)

Figure 135-4. A, A 7-year-old boy with two separate 7- to 9-mm stones within lower pole calyces (left arrow). A ureteroscopic approach was attempted, but a lower pole infundibular-ureteropelvic junction angle greater than 270 degrees (right arrow) limited ureteroscopic access and visibility. B, A percutaneous nephrolithotomy was subsequently performed, clearing all stones in one sitting.

semirigid ureteroscopy for ureteral calculi is routinely performed with a safety wire in place, and flexible ureteroscopy is performed with a safety wire and a working wire in place. Ureteral access sheaths (internal diameter of 9.5 Fr) are routinely used to facilitate flexible ureteroscopy, especially in cases of large proximal ureteral stones and heavy renal pelvis stone burdens. Access sheaths also may facilitate flexible ureteroscopy when altered anatomy or tortuous ureters are encountered (Fig. 135-5).

Irrigating fluid, which may be used under pressure, should be isotonic and body temperature to avoid hyponatremia and hypothermia. Calculi are basket extracted when feasible or fragmented using a holmium:YAG laser to facilitate removal. The decision to place a ureteral stent postoperatively is based on the duration of the procedure, the number of passes with the ureterscope, and the degree of visible ureteral trauma or edema at the conclusion of the procedure. If the child can tolerate leaving a urethral string in place for 3 days to 1 week, the patient's parents are asked to remove the stent at home, otherwise the stent is removed under brief anesthetic after 7 days.

Limitations and Complications

As ureteroscopy is becoming more prominent in the armamentarium of the pediatric endourologist, complications need to be anticipated, and unanswered questions need to be addressed. **The most common complications involve unrecognized ureteral injury including mucosal flaps and tears, perforation, false passage, and partial to complete avulsion.** Mitigating the damage by early recognition and temporizing with immediate discontinuation of the procedure and passage of a ureteral stent may avoid complications related to shear force injury on the ureter, ischemic damage, and extravasation of irrigant or urine. Injury can occur during introduction of the ureterscope or either antegrade or retrograde passage of instrumentation (guidewires, baskets, dilators), especially in the area of an impacted ureteral calculus. Attempting to withdraw a basket-entrapped calculus too large for the ureter to accommodate can result in any of the above-mentioned injuries. In postpubertal children with an adult body mass, ureteroscopic access is technically similar to in adults. However, in prepubertal children, whether

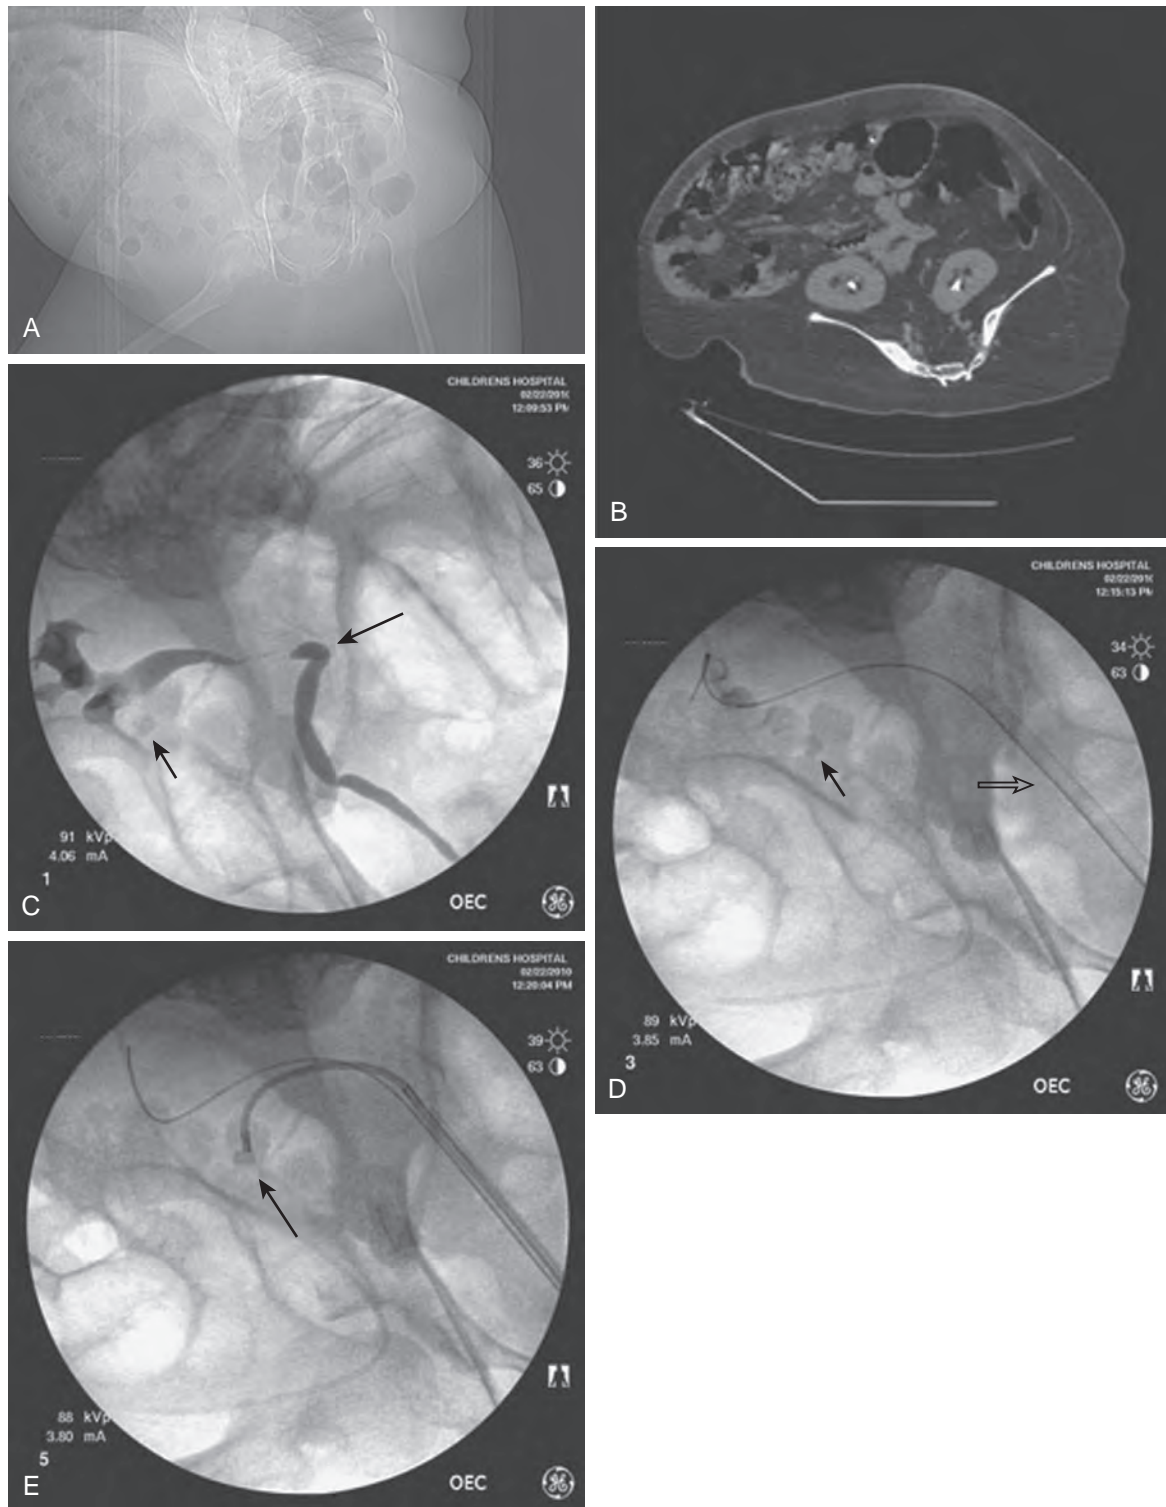

Figure 135-5. Altered anatomy in a 17-year-old boy with spina bifida who underwent a high thoracic myelomeningocele closure at birth (A). A computed tomography scan performed for a gross hematuria workup revealed bilateral nephrolithiasis in pelvic kidneys (B). The right retrograde pyelogram (C) demonstrated the lower pole stone (*short arrow*) and a tortuous ureter almost taking a perpendicular course (*long arrow*). Placement of a ureteral access sheath (D) straightened the ureter (*open arrow*). This allowed easier access to address the stone (*short arrow* in D) with a flexible ureteroscope (E).

or not to attempt primary treatment without ureteric orifice dilation, perform dilation at the time of definitive therapy, or place a stent and allow the ureter to passively dilate before definitive therapy remains uncertain. [Herndon and colleagues \(2006\)](#) performed semirigid ureteroscopy (4.5 Fr and 6.5 Fr) in 29 children with a mean age of 11 years for distal ureteral calculi. With no ureter actively dilated and only 14% of children receiving a stent beforehand, the ureter was accessed in 100% of cases for a stone-free rate of 96% ([Herndon et al, 2006](#)). We can further validate this report with our own institutional experience using 6.9-Fr flexible and 4.5-Fr and 6.5-Fr semirigid ureteroscopy; however, we prefer to perform sequential dilation with the 8/10-Fr coaxial dilator even in very young children. If we encounter difficulty, we place a stent rather than dilate more aggressively. This approach appears to minimize the immediate risks and potential long-term complications, particularly in the management of upper tract calculi; however, it increases the number of children who require a second anesthetic and procedure to achieve stone-free status. Reports suggest that 40% of pediatric patients require at least two procedures to treat upper tract calculi, which indicates that the likelihood of achieving a stone-free status after one ureteroscopic procedure may not be significantly better than with SWL ([Corcoran et al, 2007](#)). Performance of additional procedures was reported in more than half of the stones 6 mm or larger ([Tanaka et al, 2008](#)).

The necessity of placing a stent after ureteroscopy in all children is also debated. Although the tendency in large series was to leave a stent in place after ureteroscopic manipulation in most children ([Smaldone et al, 2007](#)), several authors reported no acute or long-term sequelae despite leaving a postoperative stent in less than 20% of cases ([Herndon et al, 2006](#)). In our experience, the decision to place a stent after ureteroscopy is made on an individual patient basis and depends on surgeon experience and degree of visible ureteral trauma at the conclusion of the procedure.

KEY POINTS: URETEROSCOPIC MANAGEMENT OF UPPER TRACT CALCULI

- The combination of endoscopic miniaturization and durability with the adoption of adult ureteral access systems and techniques to the pediatric upper tract has allowed calculi measuring 15 mm to be treated effectively and safely.
- Irrigating fluid, which may be used under pressure, should be isotonic and body temperature to avoid hyponatremia and hypothermia.
- Postoperative stenting, although not clearly necessary in most uncomplicated ureteroscopic procedures, is based on the duration of the procedure, number of passes with the ureteroscope, and degree of visible ureteral trauma or edema at the conclusion of the procedure.
- The most common complications involve unrecognized ureteral injury, including mucosal flaps and tears, perforation, false passage, and partial to complete avulsion.

PERCUTANEOUS NEPHROLITHOTOMY

The safety and efficacy of percutaneous nephrolithotomy for large stone burdens have been well established in adults. Urologists initially were reluctant to perform PCNL in children because of concerns regarding the use of large instruments in pediatric kidneys and parenchymal damage and the associated effects on renal function, radiation exposure with fluoroscopy, and the risks of major complications including sepsis and bleeding. Also, a deterrent to performing PCNL in children was the potential resultant sequelae of hypothermia (i.e., coagulopathy) from prolonged exposure to irrigation. However, with significantly accumulated experience, PCNL is used at the present time as monotherapy and in combination with SWL (sandwich therapy) in children achieving stone-free rates ranging from 68% to 100% ([Table 135-3](#)) ([Rizvi et al,](#)

[2003](#); [Mahmud and Zaidi, 2004](#)). Although there is no current international consensus, relative indications for PCNL as a primary treatment modality in children include large upper tract stone burden (>1.5 cm), lower pole calculi larger than 1 cm, concurrent anatomic abnormality impairing urinary drainage and stone clearance, or known cystine or struvite composition ([Wu and Docimo, 2004](#); [Farhat and Kropp, 2007](#)).

The earliest pediatric PCNL series were performed using standard adult-sized instruments. [Woodside and associates \(1985\)](#) first reported a series of seven patients (age range, 5 to 18 years) who were rendered stone-free without complications using adult percutaneous techniques and equipment. [Mor and colleagues \(1997\)](#) subsequently reported another pediatric PCNL series using adult-sized instruments. These early series avoided performing PCNL in very small children (<5 years old) because of concerns regarding parenchymal damage. In contrast to these concerns, multiple series used adult-sized instruments and reported high efficacy rates with acceptable complication rates even when dilating tract size as much as 30 Fr ([Zeren et al, 2002](#); [Salah et al, 2004](#); [Samad et al, 2006](#); [Bilen et al, 2007](#)). More recent data suggested that PCNL is possible in very young children using adult-sized equipment ([Nouralizadeh et al, 2009](#)). Investigations regarding the risk of renal damage in pediatric patients treated with PCNL revealed that there is no significant risk of renal functional loss. [Mor and colleagues \(1997\)](#) performed radioisotope scans on 10 children before and after PCNL and found no change in differential function and no evidence of significant scarring.

Despite successful use of adult equipment, early efforts focused on developing technology to minimize percutaneous tract size without affecting PCNL efficacy. [Jackman and associates \(1998\)](#) developed a novel percutaneous access technique ("mini-perc") using a 13-Fr peel-away vascular access sheath and reported an 85% stone-free rate for 11 procedures in 7 children with a mean age of 3.4 years and an average stone burden of 1.2 cm² ([Fig. 135-6](#)). With this technique, PCNL could now be performed in preschool-age children. The benefits of minimal tract dilation included increased maneuverability, decreased blood loss, and shorter hospital stay. However, theoretical limitations including prolonged operative times and impaired visualization from bleeding suggest that this technique may be inadequate for very large stone burdens.

Advancements in instrumentation such as smaller nephroscopes (15 to 18 Fr), more efficient energy sources for intracorporeal lithotripsy including holmium:YAG laser, and smaller pneumatic lithoclast and ultrasound probes have greatly facilitated percutaneous treatment techniques in pediatric patients ([Fig. 135-7](#)). As a result, PCNL has replaced open surgery as the treatment of choice for large stone burdens in all children.

Planning for Percutaneous Nephrolithotomy in Children

Much planning is required before performing PCNL in children. Films must be reviewed scrupulously to determine if stones are amenable to a percutaneous procedure. For example, nephrocalcinosis in children may be confused with staghorn calculi, but the etiology and treatment are very different ([Fig. 135-8](#)). Infection is the most common causative agent in the formation of a staghorn calculus, and PCNL is a first-line treatment. The most frequent causes of nephrocalcinosis are hereditary tubulopathies and vitamin D intoxication ([Ammenti et al, 2009](#)). Medullary sponge kidney is a renal malformation characterized by cystic anomalies of precalyceal ducts that is frequently associated with nephrocalcinosis and stone formation ([Gambaro et al, 2006](#)). Nephrocalcinosis is most often not amenable to endourologic treatment because calculi are intraparenchymal and outside the collecting system. Management is often medical and aimed at prevention of further nephrocalculi, a cause of worsening renal function.

The risks of PCNL must be reviewed with the consenting parent or guardian. It must be understood that a percutaneous procedure carries risks that include, but are not limited to, bleeding requiring transfusion, delayed renal hemorrhage requiring

Figure 135-6. The mini-perc set uses an 11-Fr to 13-Fr peel-away vascular access sheath to accommodate a ureteroscope or cystoscope, serving as a nephroscope, to perform percutaneous nephrolithotomy in children of preschool age.

Figure 135-7. Smaller caliber nephroscopes (15 to 18 Fr) with offset lenses have greatly facilitated standard percutaneous treatment techniques in pediatric patients. (From Wolf JS Jr, Bennett CJ, Dmochowski RR, et al. Best practice policy statement on urologic surgery antimicrobial prophylaxis. J Urol 2008;179:1379-90.)

Figure 135-8. A 9-year-old boy with cerebral palsy and gross hematuria. Computed tomography scan demonstrated bilateral nephrolithiasis (A) thought to be staghorn calculi. Plain radiograph (B) and bilateral retrograde pyelograms (C and D) correlate to show nephrocalcinosis (white circles in B and arrows in C and D) reflective of medullary sponge kidney disease. Subsequent metabolic workup revealed renal tubular acidosis with hypercalciuria.

angioablation, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney.

Every attempt should be made to treat a urinary tract infection and/or minimize bacteriuria before the procedure. A urine culture, with antibiotic sensitivities, should be checked 3 weeks before the procedure. A positive culture requires a full course of antibiotics and repeat culture to confirm. A 3- to 5-day course of prophylactic antibiotics is recommended before the procedure, even with a negative preoperative culture. Broad-spectrum intravenous antibiotics (i.e., ampicillin and gentamicin) should be given at the time of the procedure.

All percutaneous procedures are performed using general anesthesia. A warm operating room, warmed isotonic irrigation solution, short operative times (not to exceed 1.5 hours), proper draping, and monitoring of body temperature should decrease the incidence of hypothermia and hyponatremia. After induction of anesthesia with the patient in the lithotomy position, a retrograde pyelogram is obtained to outline the collecting system, and an occlusive balloon or a 5-Fr open-ended ureteral catheter is left in situ to opacify the collecting system during percutaneous access. The patient is repositioned in prone with the torso elevated 30 degrees from the table surface with a towel roll (Farhat and Kropp, 2007).

Circumstances that require special consideration involve children with spinal cord injuries and congenital anomalies such as spina bifida. In these patients, positioning can be a challenge because of existing spinal hardware and limb contracture (Fig. 135-9) (Ost and Lee, 2006). Patients who have had prior spinal surgery consisting of vertebral fusion or Harrington rod placement have restricted spinal mobility, spinal curvature, or atrophic or contracted extremities (Fig. 135-10). Renal anatomy is altered secondary to scoliosis, lordosis, or kyphosis. As a consequence, the risk of injuries to adjacent organs (i.e., pneumothorax) during percutaneous procedures increases. Assessing the degree of mobility in the trunk and extremities is crucial in planning for PCNL in these patients (Fig. 135-11). These patients must be placed in the most comfortable position possible without excessive contortion or flexion of the joints. Special attention must be paid to latex precautions in patients with myelomeningocele, and as in all cases, proper padding of pressure points is mandatory.

Percutaneous Nephrolithotomy Technique in Children

After selection of the desired calyx, a 16-gauge or 18-gauge spinal needle is placed with the assistance of fluoroscopy in the 30-degree position. The ideal tract is one that provides the shortest and most direct access to the stone. For complex calculi occupying multiple calyces including the lower pole, a supracostal posterior access is preferred to provide visualization of the superior calyx and pelvis, access to the pelvis and ureter, and straight access to the inferior calyces allowing easier manipulation of the working instruments and minimizing torque on the collecting system (El-Nahas et al, 2008). After the initial puncture, no attempt should be made to redirect the needle while it is located within the cortex of the kidney to avoid trauma. With the C-arm in the 90-degree plane, the depth and medial extension of the needle are checked. After access is confirmed with urine or irrigation return, a flexible guidewire is placed into the collecting system through the needle and directed down the ureter into the bladder. A small skin incision is made with a No. 11 scalpel and 8-Fr and 10-Fr coaxial dilators are passed over the guidewire into the collecting system. Once in place, an Amplatz Super Stiff guidewire is placed as a working wire.

Tract dilation can be performed by several techniques. The most common technique employed is serial dilation with Amplatz dilators over working wires and subsequent sheath placement under fluoroscopic guidance. For smaller children and lower stone burdens, an 11-Fr to 13-Fr peel-away sheath (Docimo Mini-Perc; Cook Urological Inc., Spencer, IN) and trocar are passed over the wire and through the calyx under fluoroscopic guidance. For balloon dilation, either the Bard X-Force or the NephroMax High Pressure Nephrostomy Balloon Catheter (Boston Scientific, Marlborough, MA) may be used. Both catheters facilitate dilation of a 30-Fr tract at a pressure of 17 atm. This technique permits dilation and sheath placement in a single step, minimizing potential parenchymal trauma and bleeding from sequential dilation with rigid dilators. The decision to proceed with mini-perc or dilation is individualized based on the child's age, anatomy, and stone burden; however, familiarity with all of the above-described techniques facilitates complete access with minimal morbidity (Fig. 135-12A and B).

Once access is obtained, nephroscopy and nephrolithotomy can be performed with a variety of energy sources for stone

Figure 135-9. A, Severe scoliosis and complete staghorn calculus (arrow) in a 10-year-old patient with partial quadriplegia. B, Spinal curvature and limb contractures (left arm) prevented optimal prone positioning. Care is taken to pad all joints in the prone position.

Figure 135-10. A, Harrington spinal rods in a 16-year-old patient with spina bifida. B, Prone view of right collecting system showing midpole calyceal stone as filling defect (arrow). Hardware obscured the proximal ureter and impeded access to this calyx when the C-arm was in the 30-degree position.

Figure 135-11. A, A 14-year-old boy with spina bifida and scoliosis with a left upper pole partial staghorn calculus (arrow). B, Altered spinal anatomy had deflected renal anatomy cephalad (arrow). Intercostal access between the 10th and 11th rib increases the risk of pneumothorax considerably.

fragmentation. The outer diameter of nephroscopes ranges from 15 to 26 Fr. A 15-Fr flexible nephroscope with a 6-Fr working channel also has been developed. In addition, 7-Fr and 8-Fr offset cystoscopes with 5-Fr working ports and 7- to 9-Fr flexible ureteroscopes can be used through an 11-Fr access sheath with enough clearance to allow low-pressure irrigation (Wu and Docimo, 2004). Energy sources used include ultrasonic lithotripsy, electrohydraulic lithotripsy (EHL), and the holmium laser, although individual preference is determined by availability and surgeon experience. Postoperative stenting and placement of a nephrostomy tube are patient and surgeon dependent and vary among series. Similar to adult procedures, tubeless PCNL has theoretical advantages,

including decreased postoperative pain and short hospital stay, but data are limited in pediatric patients (Khairy Salem et al, 2007).

Percutaneous Nephrolithotomy Outcomes

Large retrospective series of PCNL monotherapy have demonstrated high efficacy rates approaching 90% (see Table 135-3) (Zeren et al, 2002; Desai et al, 2004; Bilen et al, 2007). In 56 children (mean age of 9.1 years) with a mean stone burden of 337.5 mm², Desai and colleagues (2004) reported a stone-free rate of 89.8% using EHL through a 14-Fr nephroscope and a 20- to 24-Fr sheath. Of these procedures, 61% required multiple tracts, and 45%

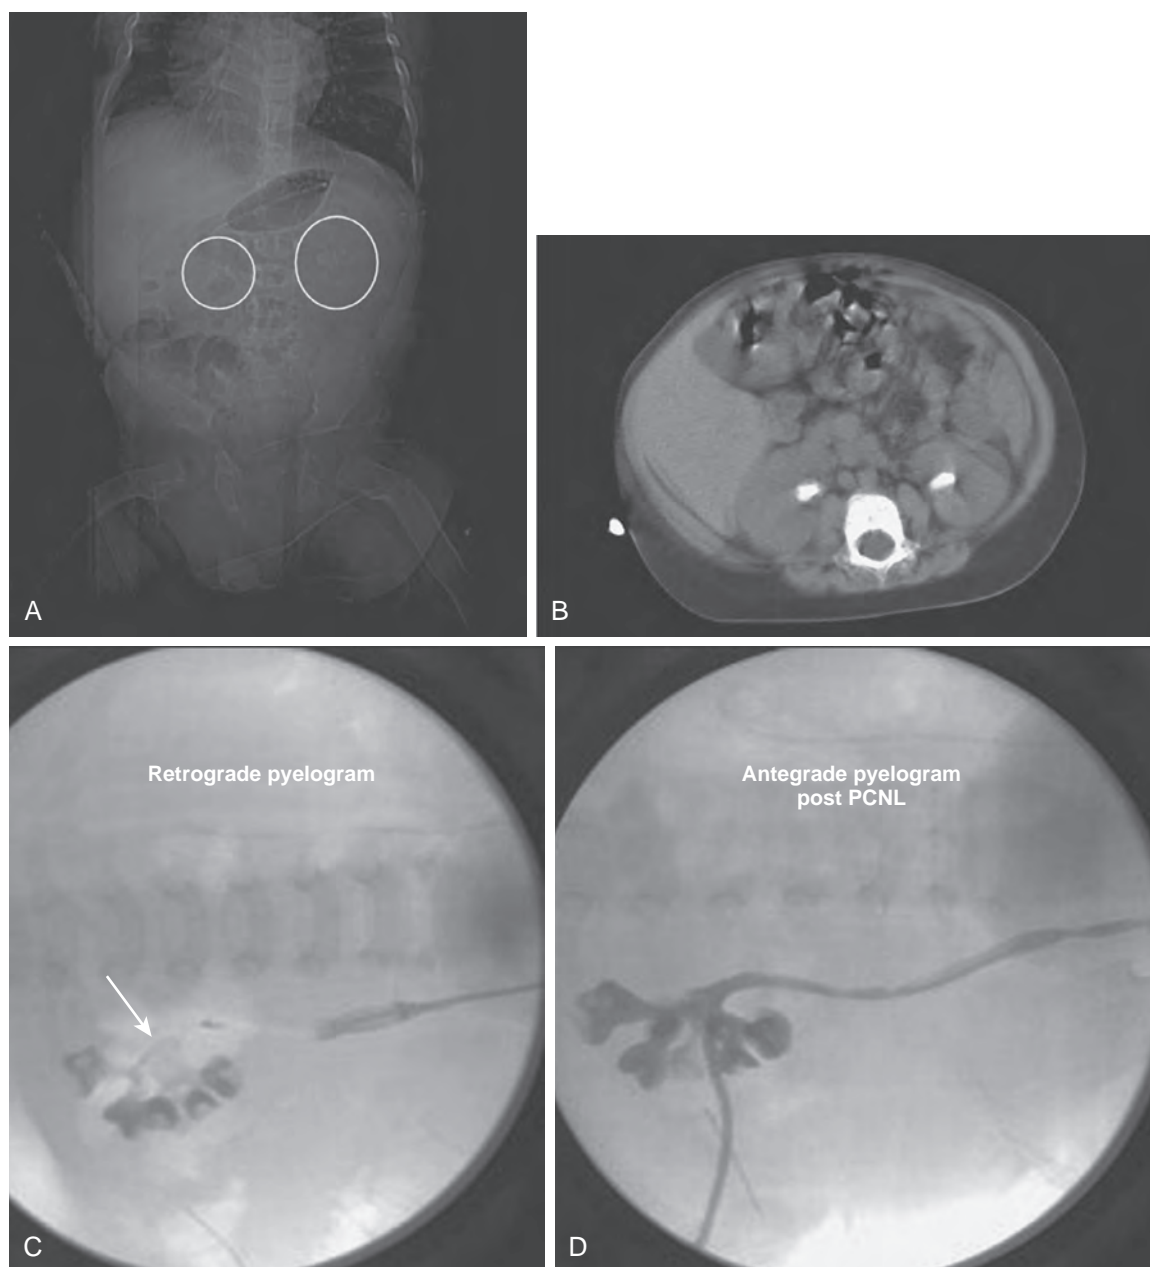

Figure 135-12. A 22-month-old boy with intractable diarrhea of infancy from tufting enteropathy who awaited a small bowel transplant. Risks for nephrolithiasis included dependency on total parenteral nutrition, osteomalacia, chronic dehydration, hypocitruria, and hyperoxaluria. **A**, Kidney-ureter-bladder film demonstrated mildly radiopaque stones. **B**, Subsequent computed tomography scan confirmed bilateral staghorn calculi. **C**, Prone view of left retrograde pyelogram of child in **A**, demonstrating staghorn calculi as a filling defect (*arrow*). A mini-perc technique was used to address the stones. **D**, Prone view of the antegrade nephrostogram through a 6-Fr nephrostomy tube demonstrating “stone-free” status. PCNL, percutaneous nephrolithotomy.

were staged procedures. Findings demonstrated that the number and size of tracts were significantly associated with postoperative hemoglobin decrease (mean 1.9 g/dL) and overall transfusion rate (14%) (Desai et al, 2004). In 52 children with a mean age of 7.9 years and a mean stone burden of 282 mm², Zeren and coworkers (2002) reported an 87% stone-free rate using ultrasonography and EHL for fragmentation and tract dilation from 18 Fr to 30 Fr. Complications included postoperative fever (30%) and need for transfusion (24%). Transfusion was associated with operative time, sheath size, and stone burden (Zeren et al, 2002). In 135 children with a mean age of 8.9 years and a mean stone burden of 507 mm², Salah and associates (2004) reported a 98.5% stone-free rate using

ultrasonography through a 26-Fr nephroscope. Complications were low (8% urine leak rate and .7% transfusion rate), with only one patient requiring a second procedure (Salah et al, 2004). In a series of 46 children with a mean stone burden of 332 mm², Bilen and coworkers (2007) reported an 88% stone-free rate using EHL, ultrasonography, and the holmium laser. When stratified by tract size (14 Fr, 20 Fr, and 24 Fr), efficacy rates were similar in all groups, but there were no complications or transfusions in the 14-Fr tract group (Bilen et al, 2007). A large multicenter study demonstrated that the most significant determinants affecting complication rates were operative time, sheath size, midcalyceal puncture, and partial staghorn formation (Onal et al, 2014).

In an effort to reduce the number of tracts and associated morbidity, some centers follow primary PCNL with adjunctive SWL therapy to clear RFs. In a small series of 29 children with a mean age of 3.8 years and a mean stone burden of 2.4 cm, [Mahmud and Zaidi \(2004\)](#) reported a 60% stone-free rate after PCNL monotherapy using EHL through a 17-Fr angled nephroscope. Only one tract was used in all patients, and after SWL sandwich therapy, the stone-free rate increased to 100% ([Mahmud and Zaidi, 2004](#)). In a larger series of 169 children with a mean stone burden of 3.1 cm, [Samad and colleagues \(2006\)](#) reported a 59% monotherapy stone-free rate with 96% of cases performed through a single tract. Approximately one third (34.5%) of primary failures were treated with SWL; the cumulative stone-free rate in all patients was 93.8% with a 3.6% transfusion rate ([Samad et al, 2006](#)). When stratified by age, anatomy, bilaterality, and renal function, stone-free outcomes were equivalent in all groups. The decision to follow PCNL with SWL is related to operator experience with percutaneous technique and available technology. **We prefer to perform a second-look nephroscopy through the original tract to ensure stone-free status during the initial hospital admission rather than progress to SWL sandwich therapy.** Endoscopic surveillance during the initial procedure can determine the need for second-look nephroscopy without relying on additional imaging and the associated risks of radiation exposure ([Roth et al, 2009](#)). With continued improvement in technology and technique, the indications for PCNL in children are expected to continue to increase. PCNL is technically challenging, and surgeon experience with PCNL is paramount in developing individualized treatment plans to optimize efficacy with minimal morbidity.

KEY POINTS: PERCUTANEOUS NEPHROTHOTOMY

- Relative indications for PCNL as a primary treatment modality in children include large upper tract stone burden (>1.5 cm), lower pole calculi larger than 1 cm, concurrent anatomic abnormality impairing urinary drainage and stone clearance, and known cystine or struvite composition.
- A urine culture before PCNL is required, and prophylactic antibiotics 3 to 5 days before the procedure are recommended despite a negative preoperative culture to minimize bacteriuria.
- Despite efficacy rates approaching 90%, PCNL is associated with risks including bleeding, delayed renal hemorrhage, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney.

LAPAROSCOPIC AND ROBOTIC-ASSISTED PYELOLITHOTOMY

Treatment of large stone burdens in children is technically challenging and often requires multiple procedures. Laparoscopy and robotic-assisted laparoscopy have been used successfully in adults for treatment of calculi during the concomitant treatment of ureteropelvic junction obstruction and in the primary treatment of staghorn calculi. Small series using these techniques in children have been described only more recently. In eight children (mean age of 4 years) with a mean stone burden of 2.9 cm undergoing transperitoneal laparoscopic pyelolithotomy, [Casale and coworkers \(2004\)](#) reported a 100% success rate, a mean hospital stay of 2.15 days, and a mean operative time of 1.6 hours with no major complications. In the first report of robotic-assisted laparoscopic pyelolithotomy, [Lee and associates \(2007\)](#) described their experience in five patients: four with cystine staghorn calculi refractory to PCNL and SWL and one with calcium oxalate calculi and concurrent ureteropelvic junction obstruction. Of these cases, four were completed robotically, with one patient having a residual 6-mm lower pole stone and one patient requiring conversion to an open procedure. Mean operative time in this series was 315 minutes, mean estimated

blood loss was less than 20 mL, and the mean hospital length of stay was 3.8 days ([Lee et al, 2007](#)). These early experiences demonstrate that laparoscopic pyelolithotomy is feasible, safe, and efficacious as an alternative to open pyelolithotomy in children and warrants further study. However, because of their demanding technical nature, these procedures are likely to be limited to endourologic management failures in academic centers with abundant expertise in laparoscopic and robotic pediatric surgery.

PERCUTANEOUS CYSTOLITHOTRIPSY FOR BLADDER STONES

Bladder stones are found more often in children from developing countries and are thought to be related endemically to malnutrition. It is thought that diets low in animal protein and phosphorus (breast milk as opposed to cow's milk) in addition to vitamin A deficiency are contributory ([Kancha and Anasuya, 1992](#)). **Bladder stones from children in these developing countries are most often composed of ammonium acid urate.** In contrast, among children from industrialized nations, bladder stones are most often found in children with spinal cord injuries and/or congenital abnormalities such as spina bifida. These children often have undergone augmentation cystoplasty and/or manage their bladders by clean intermittent catheterization. **It has been reported that 50% of those children with reconstructed bladders develop bladder stones in their lifetime** ([Palmer et al, 1993](#)). Urinary stasis, bacterial colonization or infection with urea-splitting organisms, retained mucus, and foreign bodies all can contribute to the formation of bladder stones, most of which are struvite.

Open cystolithotomy has been the traditional modality to treat bladder stones. Transurethral cystolithotripsy is an alternative, although it is not ideal in pediatric patients. In children, a smaller caliber urethra limits effective treatment of large bladder stone burdens. However, percutaneous cystolithotripsy is used worldwide with the advantage of shorter hospital stays, smaller scars, and less indwelling catheter time postoperatively ([Al-Marhoon et al, 2009](#)). At the present time, percutaneous cystolithotripsy is the preferred method to treat bladder stones that have formed in reconstructed bladders ([Paez et al, 2007](#)). In developing countries, percutaneous lithotripsy has become the first-line treatment modality to address bladder stones in bladders that have not been augmented. For example, [Salah and colleagues \(2005\)](#) reported on their experience with cystolithotripsy in 155 children from Pakistan and Yemen with a mean age of 4.5 years and average bladder stone burden of 2.3 cm (range, 0.7 to 4 cm). All children were treated safely and successfully using a 26-Fr nephroscope through a 30-Fr sheath placed through a 1-cm suprapubic incision ([Salah et al, 2005](#)).

Percutaneous cystolithotripsy has been used effectively in infants younger than 1 year to clear bladder stones. [Gan and colleagues \(2010\)](#) reported on their experience using a 16-Fr peel-away sheath with a ureteroscope to treat bladder stones with an average size of 1.4 cm in 15 boys with a mean age of 8.2 months.

Percutaneous cystolithotripsy in children may be performed under ultrasound or fluoroscopic guidance and is most often an outpatient procedure. With either modality, the bladder is first filled to capacity with water or contrast material. The child is placed in Trendelenburg position to minimize the risk of bowel injury during access and tract dilation/formation. An 18-gauge needle is placed into the distended bladder midline, one to two fingerbreadths above the pubic bone. When proper placement is confirmed with return of fluid, a wire is passed through the needle into the bladder. A tract may then be established reflective of stone diameter and child size. Most often, a tract is established with a balloon dilator to accompany a 30-Fr sheath. Amplatz dilators also may be used. A 26-Fr nephroscope is used to extract stones smaller than 1 cm with a rigid stone forceps, or an ultrasonic lithotripter may be used to fragment stones larger than 1 cm. At the conclusion of a percutaneous cystolithotripsy procedure, a Foley catheter is left per urethra or per continent catheterizable stoma for 1 week. The rectus fascia defect is closed with a 2-0 Vicryl suture ([Fig. 135-13](#)).

Figure 135-13. A 12-year-old boy with spina bifida with an augmented bladder (ileocystoplasty) found to have multiple sizeable bladder stones (A) on a workup for recurrent *Proteus mirabilis* infections. B, Percutaneous cystolithotripsy with an ultrasonic lithotripter was performed through a 30-Fr access sheath (arrow), clearing all stones from the augmented bladder.

KEY POINT: BLADDER STONES

- Of children with reconstructed bladders, 50% develop bladder stones in their lifetime. Urinary stasis, bacterial colonization or infection with urea splitting organisms, retained mucus, and foreign bodies all can contribute to the formation of bladder stones, most of which are struvite.

DETERMINATION OF STONE-FREE STATUS

As the surgical management of pediatric stone disease evolves, the lack of a consistent definition of “stone-free” after definitive therapy is an issue that remains unaddressed. Although controversial, in select adult patients, all RFs can be considered clinically significant and can lead to stone recurrence (Krambeck et al, 2008). Likewise, the presence of RFs in children has been associated with poor outcomes (Afshar et al, 2004), and any size RF in a young stone former may result in the need for repeat surgical procedures. RFs smaller than 4 mm in children require a high reintervention rate; 40% of these children become symptomatic, and 20% experience stone regrowth (Dincel et al, 2013). However, these RFs often are not detected on ultrasound scan or KUB film necessitating reliance on CT imaging in select children.

Balancing the risks of radiation exposure for post-treatment stone detection and the risks of anesthesia for secondary procedures is a challenging dilemma for contemporary pediatric endourologists. Newer, high-speed helical CT scanners reduce radiation exposure and rarely require intravenous sedation. In addition, maximizing intraoperative fragment detection by direct visualization in ureteroscopy and PCNL and continued development of high-resolution real-time fluoroscopy may result in less reliance on postoperative imaging and decrease the need for second-look nephroscopy/ureteroscopy, SWL, or sandwich therapy (Ost and Lee, 2006). Until the risks of radiation exposure in children are more clearly defined, surveillance in these children will be individualized based on age, anatomy, stone burden, and underlying metabolic abnormalities.

CONCLUSIONS

Evolution of technique and miniaturization of instruments have changed the management of pediatric stone disease. However, despite encouraging results, concern remains regarding safety of endourologic treatment in smaller patients and its subsequent effects on the growing kidney. Although SWL is still considered first-line therapy for upper tract calculi smaller than 1.5 cm, evidence is accumulating that ureteroscopy with laser lithotripsy and stone basketing may be more efficacious in treating upper tract stone disease in children. PCNL remains the most effective technique for large upper tract stone burdens; however, there are reports of laparoscopic and robotic-assisted laparoscopic pyelolithotomy in major pediatric academic centers with extensive laparoscopic and robotic experience. Prospective studies designed to determine the “preferred” endourologic approach to upper tract calculi in children would be helpful, albeit difficult to conduct. In this regard, individual surgeon experience and comfort level weigh heavily in choosing a treatment modality. Familiarity of pediatric urologists with percutaneous renal access and the full spectrum of endourologic equipment and techniques will continue to facilitate efficacious, minimally invasive approaches to the entire pediatric urinary tract.

ACKNOWLEDGMENT

We acknowledge Marc C. Smaldone, MD, for his help in preparing this chapter.

SECTION D Lower Urinary Tract Conditions

136 Development and Assessment of Lower Urinary Tract Function in Children

Chung Kwong Yeung, MBBS, MD, PhD, FRCS, FRACS, FACS, Stephen Shei-Dei Yang, MD, PhD, and Piet Hoebeke, MD, PhD

Normal Lower Urinary Tract Function in Infants and Children

Epidemiology and Terminology of Lower Urinary Tract Dysfunction in Children

Bladder and Bowel Dysfunction

Clinical Assessment of Lower Urinary Tract Conditions in Children

Summary

Our increasing understanding and recognition of non-neurogenic lower urinary tract (LUT) dysfunction as a cause of various urologic disorders in childhood has had a profound influence on our management strategies over the last decade. What was known as primary or idiopathic, such as primary vesicoureteric reflux or primary nocturnal enuresis, is often associated with underlying LUT dysfunctions (LUTDs) evident on urodynamics and resolves with successful correction of the bladder physiology (Koff and Murtagh, 1983; Homsy et al, 1985; Watanabe et al, 1994; Yeung et al, 1998, 1999). Conversely, failure of recognition and treatment of the associated problem can result in persistence or even further deterioration.

The understanding of the spectrum of dysfunction of the LUT and even of normal LUT physiology in infants and young children is complex. Not only are the dynamics and functional disturbances of the LUT very different from those in adults, but the evolution in normal bladder-sphincteric function during growth and maturation in children poses continuous changes (Yeung et al, 1995a, 1995b; Sillen et al, 1996; Holmdahl, 1997). More confusingly, one type of LUTD often may progress with time and evolve imperceptibly into another, without a sharp distinction between the different stages. This is further confounded by a lack of age- and sex-specific normal reference values for various urodynamic parameters, especially for the very young age groups (Yeung et al, 1995b).

Recent advances and development in the use of urodynamic techniques specially designed for infants and young children have allowed more accurate assessment of LUT function and provided much better understanding of LUT pathophysiology. This has allowed for better recognition of functional disorders and provided a scientific basis for therapy (Hjalmas, 1988; Perez et al, 1992; Bauer, 1997; Norgaard et al, 1998). In view of the important association of LUT dysfunctions with various common urologic disorders, urologists should be acquainted with the spectrum of dysfunction and the techniques to facilitate proper diagnosis and treatment.

NORMAL LOWER URINARY TRACT FUNCTION IN INFANTS AND CHILDREN

Anatomy of Bladder

The bladder is a unique organ of the human body in that not only does it carry a dual function of both storage and emptying of urine but it also has a complex innervation of voluntary and involuntary control of function. Understanding of the functional anatomy of the LUT stems from extensive postmortem studies carried out over decades (Gosling et al, 1981; Gosling, 1985; DeLancey, 1988; de Groat, 1993; Zvara et al, 1994).

The bladder is an abdominal organ and when full can be readily palpable in infants and young children because of a shallow pelvis (Wiegel, 1990). The bladder wall consists of three layers: mucosa, detrusor, and adventitia. The detrusor consists of a meshwork of smooth muscle fibers arranged into a single functioning unit with an ability to elicit nearly maximum active tension over a wide range of length. This allows the bladder to fill with urine from the upper tract at low pressures (compliance) (Mattiasson, 1994). The ability of the bladder to store urine (reservoir function) is determined by the concomitant activity of the detrusor muscle and the bladder outlet (consisting of the bladder neck, proximal urethra, and striated muscle of the pelvic floor) (de Groat, 1993).

The bladder sphincter (external and internal) plays a major role in urinary continence by closure of the bladder neck and proximal urethra. The anatomy of the external urinary sphincter consists of a cylindric structure, which is accentuated anteriorly and thinned or actually absent posteriorly, thus giving a characteristic horseshoe or ω shape on cross section. It has an inner layer of smooth muscle and an outer layer of striated muscle, extending from the apex of the prostate to invest the length of the membranous urethra in males. In females this is less well developed and extends from the bladder neck to the mid-urethra. The internal sphincter, however,

has not been well delineated anatomically. It has generally been accepted that it consists of smooth muscle fibers continuing from the bladder base and trigone that traverse inferiorly through the bladder neck to extend toward the proximal urethra. Its existence has been better delineated on radiologic and urethral pressure measurement studies. During micturition, the bladder base, bladder neck, and proximal urethra can be shown to contract simultaneously as a unit, producing a funneling effect that opens up the bladder outlet with initiation of voiding.

Little, too, is known about the natural course of development or maturation of the structure and function of the sphincter mechanism. The literature suggests that immature detrusor-sphincter coordination, manifested as detrusor hypercontractility and interrupted voiding, commonly occurs in the first 1 to 2 years of life, causing some degree of functional bladder outflow obstruction (Sillen et al, 1992; Yeung et al, 1998). In a postmortem study of the ontogeny of the external urinary sphincter in human fetuses, infants, and young children, Kokoua and colleagues (1992) found significant age-related differences in the histologic structure of the sphincter compared to that in adults. Striated muscle fibers of the sphincter first appeared at approximately 20 weeks of gestation, then became arranged in a concentric pattern as a closed ring, fused posteriorly to form a tail-like structure that was directed to the perineal body. Posterior splitting of the striated sphincter, starting first caudally and progressively in a cephalad manner occurred during the first year of life, coinciding in parallel with gradual resorption of the "tail," eventually giving way to a mature ω -shaped structure (Kokoua et al, 1992). Because a complete closed ring of striated sphincteric muscle was present up to 1 year of age in over 40% of cases, it may be conjectured that this could be related to the high intravesical pressures and interrupted voiding that are commonly observed

during urodynamic studies in infants (Sillen et al, 1992; Yeung et al, 1995b, 1998).

Innervation of Bladder

Activation, coordination, and integration of various parts of the bladder-sphincteric complex involves both the central somatic and autonomic nervous systems through three sets of peripheral nerves: sacral parasympathetic (pelvic nerve), thoracolumbar sympathetic (hypogastric nerves and sympathetic chain), and sacral somatic nerves (primarily the pudendal nerve) (de Groat, 1993; Mattiasson, 1994) (Fig. 136-1).

Parasympathetic nerve fibers run in the pelvic nerve (S2 to S4) to supply the pelvic and vesical plexuses before entering the bladder. Parasympathetic ganglia are found within these plexuses and in the bladder wall. Sympathetic nerves arise from segments T10 to L2 of the spinal cord and go to the inferior mesenteric ganglion through the sympathetic trunk. From the inferior mesenteric ganglion the nerve fibers pass to the pelvic plexus and bladder through the hypogastric nerves. There is also sympathetic innervation originating from T10 to L2 supplying the detrusor and urethral sphincter (Bradley et al, 1974). The somatic nervous system (pudendal nerve) supplies the periurethral pelvic floor musculature (Mattiasson, 1994). The sensory and motor nerve fibers carried by all three nerves innervate both the bladder and urethral sphincter. They originate from parasympathetic ganglia located in the second, third, and fourth segments of the sacral spinal cord (Bradley et al, 1974). Within the spinal cord, information from bladder afferents is integrated with that from other viscera and somatic sources and projected to the brainstem centers that coordinate the micturition cycle (Harrison and Abrams, 1994).

Figure 136-1. Diagram to illustrate the innervation of the bladder-sphincter complex. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Saunders; 2010. p. 353–65.)

Development of Normal Lower Urinary Tract Function and Micturition Control

Urodynamic studies on normal infant bladders have shown that LUT function in young children is very different from that in adults. During the first 2 to 3 years of life there is progressive development from an initially indiscriminate infantile voiding pattern to a more socially conscious and voluntary or adult type of micturition. This is achieved through an active learning process whereby the child acquires the ability to voluntarily inhibit or initiate voiding at socially convenient times. This natural evolution of bladder control entails an intact nervous system and depends on at least three main events occurring in parallel: (1) a progressive increase in bladder functional storage capacity, (2) maturation of voluntary control over the urethral striated muscle sphincter, and, perhaps most importantly, (3) development of direct volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit the micturition reflex. This process also can be influenced by an awareness of the accepted social norms in families during toilet training (Yeung, 2001).

Change in Lower Urinary Tract Functional Parameters

Voiding Frequency. During the third trimester of pregnancy, the fetus is voiding at the rate of approximately 30 times every 24 hours (Goellner et al, 1981). However, immediately after birth, this drops dramatically for the first few days of life, only to increase again after the first week to reach a peak by week 2 to 4 to an average of once per hour. Subsequently this rate declines again to approximately 10 to 15 times per day between 6 to 12 months and to about 8 to 10 times per day by 2 to 3 years (Goellner et al, 1981; Yeung et al, 1995b; Holmdahl et al, 1996). This reduction in voiding frequency observed during the first few years of life appears to be related mainly to an increase in bladder volume in parallel to body growth, which is proportionately greater than simultaneous increase in urine volume production (Yeates, 1973; Koff, 1997). By the age of 12, the voiding pattern is very similar to that in an adult and usually comprises 4 to 6 voids per day (Fig. 136-2).

Bladder Volume and Emptying Efficiency. The increase in bladder volume with the growth of the child is a crucial step in the development of bladder function and urinary continence. An adequate reservoir function for urine storage is necessary to meet the increased rate of urine production and decreased voiding frequency in the growing child.

Figure 136-2. Changes in voided volume and micturition frequency from neonates to early infancy.

Several studies have shown that the age-related expected bladder capacity—that is, the maximum voided volume at a certain age—can be accurately estimated and expressed as a function of age with no difference in sex. For young infants it can be expressed as follows (Holmdahl et al, 1996):

$$\text{Expected bladder capacity (mL)} = 38 + 2.5 \times \text{Age (months)}.$$

For older children, the most widely accepted formulas include Koff's formula (Koff, 1983):

$$\text{Expected bladder capacity (mL)} = [\text{Age (years)} + 2] \times 30.$$

Or, similarly, Hjalmas' formula (Hjalmas, 1976, 1988):

$$\text{Expected bladder capacity (mL)} = 30 + [\text{Age (years)} \times 30].$$

In parallel to the increase in bladder volume, the mean voided volume of each micturition increases with age. Of note, urodynamic studies have shown that a significant proportion of infants with incomplete maturation of detrusor-sphincter coordination before the age of 1 year are still able to achieve satisfactory bladder emptying (>80% efficacy) (Yeung, 1995; Yeung et al, 1995b, 1998; Holmdahl et al, 1996; Bachelard et al, 1999; Sillen et al, 2000).

Detrusor Pressure at Voiding. Limited studies have been done on detrusor pressures at voiding in normal infants, because of the technical difficulties involved in performing urodynamic studies in young infants and an ethical consideration in justifying doing so. From the data we have in a natural filling cystometric study of infants with normal LUTs (as indicated by a normal micturating cystourethrogram) and who had undergone either dismembered pyeloplasty for pelviureteral junction obstruction or nephrectomy for dysplastic kidney, we have documented significantly higher maximum detrusor pressures with micturition ($P_{\text{det,max}}$) than in normal adults. It was also noted that male infants voided with significantly higher pressures than females (mean $P_{\text{det,max}}$: 118 vs. 75 cm H_2O , respectively, $P < .03$) (Yeung et al, 1995a, 1995b, 1998). Similar findings were reported in healthy, asymptomatic infant siblings of children with vesicoureteral reflux (Bachelard et al, 1999).

Studies also have shown that these high detrusor pressures noted during micturition were mainly observed only during the first year of life and decreased progressively with age. Furthermore, an interrupted or "staccato" type of urinary stream was noted in over half of the patients (Yeung et al, 1995a, 1995b, 1998). This was demonstrated by fluctuations of the detrusor pressure when it reached maximum during voiding and resumption of urinary stream in conjunction with a sharp fall in the detrusor pressure. The high detrusor pressures during voiding are thought to represent variations among individual infants in the maturation process of detrusor and sphincter coordination during the first 1 to 2 years of life (Yeung et al, 1995a, 1998; Holmdahl et al, 1996; Bachelard et al, 1999; Sillen et al, 2000).

We have further confirmed this finding using video-cystometry under fluoroscopy combined with natural fill urodynamics and perineal electromyography (EMG) in infants with a history of urinary tract infections (UTIs). Periods of increase in perineal or sphincteric EMG activities were noted during voiding and associated with a sudden cessation of urinary flow with a simultaneous isometric rise or high peak of detrusor pressure. In contrast, resumption of urinary flow was associated with relaxation of the external urinary sphincter and a paradoxical drop in detrusor pressure. Also, the detrusor pressure associated with the initiation of urinary flow was usually significantly lower than the maximal detrusor pressure during micturition ($P_{\text{det,max}}$) and the $P_{\text{det,max}}$ was significantly higher than those recorded in normal adults (Fig. 136-3).

Evolution of Normal Micturition Control

Traditionally, it has been assumed that micturition in newborns and young infants occurs automatically with a full bladder by a simple

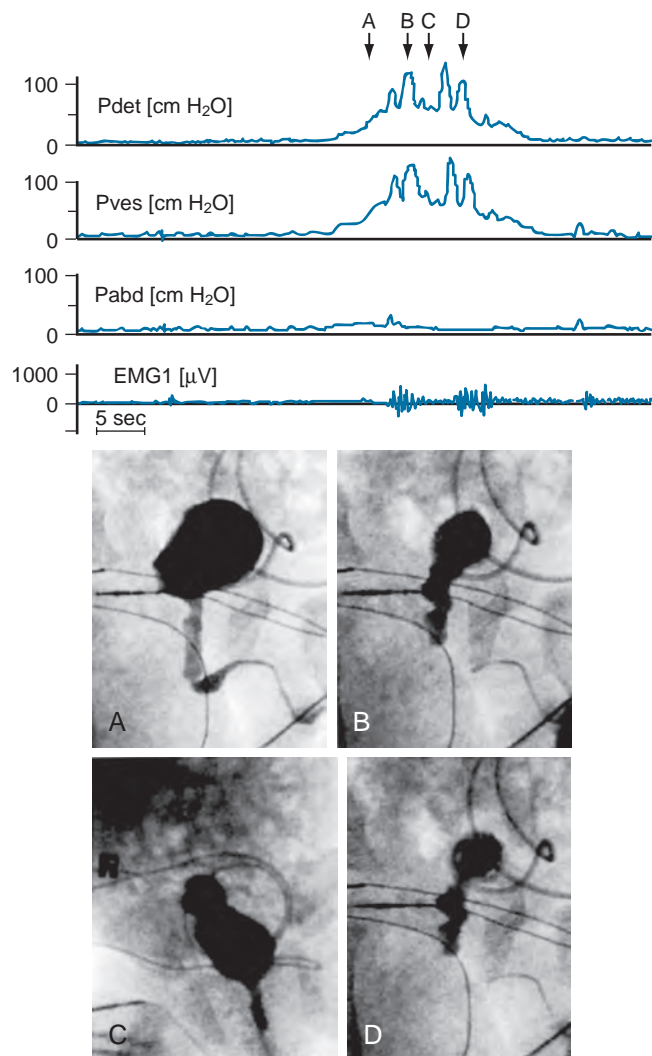

Figure 136-3. Interrupted voiding pattern due to detrusor-sphincter discoordination as revealed by urodynamic study with simultaneous perineal electromyographic (EMG) monitoring and video-cystourethrography. Arrows in top figure (graph) correspond to urethrograms at bottom. A, Urinary flow started. B, Premature sphincteric contraction and urethral closure as evidenced by the urethrogram and increase in sphincteric EMG activities, leading to a sharp spike of detrusor pressure (isometric increase) associated with a paradoxical abrupt cessation of urinary flow. C, Urinary flow resumed in parallel with sphincter relaxation. D, Repeated sphincteric contraction leading to another sharp increase in detrusor pressure and paradoxical interruption of urinary flow. Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, intravesical pressure. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Saunders; 2010. p. 353–65.)

spinal cord reflex, with little or no mediation by the higher neural centers and that with progressive maturation, voluntary inhibition of the bladder emptying reflex is achieved by adulthood. A delay in the normal maturation of bladder control was attributed to certain conditions such as primary nocturnal enuresis and hence the traditional belief that all enuretics would get better with age (Nash, 1949). However, more recent studies have indicated that this is an oversimplification of what actually occurs. Even in full-term fetuses and newborns, it has been shown that micturition is modulated by higher centers. Ohel and associates (1995) showed that intra-uterine micturition almost exclusively occurs while the fetus is awake rather than randomly distributed over various behavioral (sleep/arousal) states. Furthermore, it has been observed that mic-

Figure 136-4. Incidence of micturition during different sleep states, according to age group.

turition in a full-term fetus can be elicited by vibroacoustic stimulation, all of which indicate that the micturition reflex is probably under higher neural control even at near gestational term (Zimmer et al, 1993). Further extensive modulation occurs during the post-natal period.

Studies on normal neonates using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings have shown that even in newborns, micturition does not occur during sleep (Yeung et al, 1995b). During sleep the bladder is normally quiescent and stable with lack of facilitation of detrusor contractions, whereas during wakefulness marked detrusor overactivity is observed. Clear electroencephalographic evidence of cortical arousal or actual awakening occurs in response to bladder distention, and sleeping infants are noted to wake up before bladder activity returns and voiding occurs. However, this arousal period often may be transient, with the infant crying or moving for a brief period, micturating, and then going back to sleep without being noticed to have awakened. This waking response to bladder distention probably involves more complicated neural pathways and higher centers than has been appreciated until now (Fig. 136-4).

These results also correlate with recent animal studies showing a sophisticated integration of preexisting central and peripheral neural pathway in micturition control at birth with remodulation occurring in the early postnatal period (Maggi et al, 1986; Thor et al, 1989). Extensive studies by de Groat and colleagues (de Groat, 1993; de Groat et al, 1998; Sugaya and de Groat, 1994; Araki and de Groat, 1997; Sugaya et al, 1997) using experimental animals have indicated that early postnatal maturation of bladder function probably occurs at different levels: (1) changes in the properties of detrusor muscle; (2) developmental modifications in the peripheral innervation of the bladder; and (3) alterations in central synaptic circuitry and neuroplasticity in the parasympathetic reflex pathways to the bladder. Recordings of spontaneous activity in bladder smooth muscle in neonatal rats showed much larger amplitude and more synchronous rhythmic contractions compared to those observed in adult rats (Sugaya and de Groat, 1994). This suggests that there is a progressive reduction in intercellular communication between detrusor smooth muscle cells, resulting in less spontaneous activities and hence more efficient urine storage during early postnatal development. In addition, peripheral and central neural mechanisms also change extensively during this period. In cats (and some other species) micturition during the newborn period depends on an exteroceptive somatovesical reflex triggered when the mother licks the perineum of the kittens (de Groat et al, 1993, 1998; Araki and de Groat, 1997). This somatovesical reflex, processed in the sacral spinal cord, disappears in older animals but may reappear after spinal cord injury. Further neuroanatomic studies have indicated that spinal bladder reflexes are mediated by interneurons

located immediately adjacent to, and synapsing with, the sacral preganglionic neurons (Sugaya et al, 1997). This interneuron–preganglionic neuron synaptic transmission is very efficient immediately after birth but is very abruptly downregulated during the third postnatal week when the mature supraspinal micturition reflexes start to appear (Araki and de Groat, 1997). Transection of the spinal cord prevents this downregulation, indicating that the higher neural centers play an important role in this synaptic remodeling, which contributes to postnatal development of micturition reflexes.

During the second or third year of life there is progressive development toward a socially conscious continence and a more voluntary or adult type of micturition control. The child becomes more aware of the sensation of bladder distention and the urge to urinate, as well as the social norm and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time and then actively initiate urination even when the bladder is not very full and allow it to proceed to completion. This natural evolution of micturition control mechanisms depends on an intact neural pathway and awareness of social norms, as well as multiple factors, including the gradual increase in functional bladder capacity, maturation of detrusor-sphincter coordination and progressive development of voluntary control over the whole bladder-sphincter-perineal complex. The final steps are usually achieved at approximately 3 to 4 years of age, when most children have developed the adult pattern of urinary control and will be dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and to voluntarily initiate micturition at socially acceptable and convenient times and places. This development of continence and voluntary micturition also depends on behavioral learning and can be influenced by toilet training, which in turn depends on the cognitive perception of the maturing urinary tract. It is understandable therefore that this series of complex events is highly susceptible to the development of various types of dysfunctions.

Neurologic control of normal micturition occurs at different levels of the central nervous system, from the spinal cord with the sacral micturition center to the brainstem with the pontine micturition center, the cerebellum, basal ganglia, limbic system, thalamus and hypothalamus, and cerebral cortex (Blaivas, 1982; McLorie and Husmann, 1987; de Groat, 1993; Fernandes et al, 1994). It should be noted that the bladder is unique among visceral organs in that its function is under the control of both the somatic and the autonomic nervous systems. Besides acetylcholine and norepinephrine, various other neurotransmitters, including prostaglandin substance P, opioid peptides, vasoactive intestinal peptide, and neuropeptide Y, are involved during bladder stimulation (Fernandes et al, 1994). Simple manipulation of adrenergic and cholinergic receptors may abolish only partially the effect of neural stimulation, which explains why pharmacologic blockage of the classic neurotransmitters (acetylcholine and norepinephrine) alone may fail to elicit the expected full clinical response.

Transitory Detrusor-Sphincter Discoordination in Infancy

Studies have shown that in making the transition from an infantile to an adult pattern of micturition control, all children may transiently display some degree of abnormal bladder-sphincter function (Koff, 1997). For instance, it has been clearly shown that a significant proportion of normal infants exhibit prominent detrusor-sphincter discoordination and interrupted voiding during the first 1 to 2 years of life. This is manifested by a disordinated and interrupted urine flow that even may be brought to a complete stop for 1 to 2 minutes before restarting, producing a pattern of repeated small voidings in quick succession (Yeung et al, 1995a, 1995b, 1998). Urodynamic findings show association with high voiding pressures and interruption of flow but no impairment of overall bladder emptying. However, this type of dysfunction resolves with a period of successful toilet training and is only transitory or intermittent and does not persist. One must there-

fore be very cautious in the assessment of young children with apparent voiding dysfunctions and able to resist the temptation to overinterpret intermittent or transient symptoms as pathologic and hence overinvestigate. However, if voiding dysfunctions are persistent well beyond the period of toilet training, especially if associated with urinary complications such as recurrent urosepsis, the possibility of underlying anatomic and neurologic causes must be considered and duly evaluated.

EPIDEMIOLOGY AND TERMINOLOGY OF LOWER URINARY TRACT DYSFUNCTION IN CHILDREN

Epidemiology and Prevalence

Non-neuropathic LUTD in children is probably more common than what meets the eye, but many times present to us only when UTI, vesicoureteral reflux, or urinary incontinence is manifested. It has been reported that 15% of 6-year-old children have this condition (Hoebeke, 2002). Various conditions have been described under the category of non-neuropathic LUTD, but it must be emphasized that these conditions should not be viewed rigidly as separate and distinct entities but rather as transitional phases of a complex sequence of events. For instance, a girl with dysfunctional voiding may start with having detrusor overactivity associated with sphincter and pelvic floor overactivity, then gradually evolve to develop fractionated voiding with increasing post-micturition residues, and finally develop bladder decompensation and the “lazy bladder” syndrome (van Gool et al, 1992). It also must be emphasized that use of the term *non-neuropathic* is based purely on the fact that no obvious and neurologic lesions can be identified. However, conditions such as the urofacial syndrome complex (Ochoa syndrome) and the Hinman syndrome (severe bladder and bowel dysfunction) behave almost identically to the typical neuropathic bladder-sphincter dysfunctions. It is indeed conceivable that they do have an organic underlying neurologic cause, although the exact neuroanatomic lesion has not yet been identified. Hence, the distinction between neuropathic and non-neuropathic bladder-sphincter dysfunctions may not be as clear as traditionally thought. This chapter will focus on the discussion of non-neuropathic LUTD. Details of neuropathic LUTD will be discussed in Chapter 137.

In adults, LUT function has been well understood, and standardization of terminology has been established by a committee working under the International Continence Society (ICS) since the early 1970s (Bates et al, 1976a, 1976b, 1979). In contrast, neural control over the bladder-sphincter unit in children is age-dependent and is much more variable and complex. Definitions of normal versus abnormal LUT function therefore have been far less standardized. Various classifications for bladder dysfunctions in children have been described over the past few decades (Lapides, 1970; Bellinger, 1996; Wein, 1998). To avoid confusion, in 1998 the International Children's Continence Society (ICCS) proposed a standardized set of terminology and definitions for different LUT symptoms and dysfunctions (Norgaard et al, 1998). This was subsequently revised in 2006 and most recently in 2014 (Nevés et al, 2006; Austin et al, 2014). Terminology used in this chapter will adhere to the standard terminology as recommended by the ICCS except where specifically noted (Norgaard et al, 1998; Nevés et al, 2006; Austin et al, 2014).

Terminology of Lower Urinary Tract Symptoms

LUT symptoms (LUTS) and LUTDs are best classified according to their relation to the storage and/or emptying phase of bladder function (Norgaard et al, 1998; Nevés et al, 2006; Austin et al, 2014). Because quantitative data defining symptomatic terms are often lacking, especially in children, the ICCS standardized terminology for LUTS has focused on a descriptive rather than a quantitative language (Nevés et al, 2006; Austin et al, 2014). ICCS uses 5 years of age as the reference for LUTS, because this

age is used by the *Diagnostic and Statistical Manual Fifth Edition* (DSM-5) and the *International Classification of Disease-10* (ICD-10) to characterize urinary incontinence disorders (Chase et al, 2010). It must of course be realized that there may be significant variability in the maturation of LUT function among different children, and hence the LUTS terminology may be selectively applicable to younger cohorts of children who have already achieved good voluntary control of LUT function before 5 years of age. Of note, because symptoms are variable, the duration of any manifesting symptom is crucial in the understanding of the underlying LUTD. In addition, other variables that may have an impact on LUT function and continence, including the developmental level of the child as well as any coexisting behavioral disorders, need to be considered. For functional bowel dysfunction the minimum age is 4 years. As a result of the intricate relationship between the bladder and bowel, concomitant bladder and bowel functional disturbances are very common and these have been labeled as **bladder and bowel dysfunction (BBD)**. BBD is a comprehensive term that can further be subcategorized into LUTD and bowel dysfunction.

BLADDER AND BOWEL DYSFUNCTION

BBD is a new term presented in the third ICCS standardization document on terminology for LUT function (Austin et al, 2014) published in 2014; this enhances previous ICCS documents (Norgaard et al, 1998; Abrams et al, 2002; Nevéus et al, 2006; Dannaway et al, 2013).

The commonality of bowel emptying issues with bladder function is reflected in this new terminology. Older terms such as *Hinman bladder*, *non-neurogenic neurogenic bladder*, *occult neurogenic bladder*, and *dysfunctional elimination syndrome* have become obsolete. By this new term the close relationship between bowel and bladder function is acknowledged. Thus the importance of bowel-related terms in relation to bladder function is emphasized.

The rectum and urinary bladder have close anatomic proximity, and they share innervation from parasympathetic S2 to S4 and sympathetic L1 to L3 nerve roots. Because of this close relationship, concomitant bladder and bowel disturbances have been labeled BBD. BBD is recommended as a more descriptive comprehensive term of a combined bladder and bowel disturbance that does not explain pathogenesis but rather encompasses this parallel dysfunction. BBD is an umbrella term that can be subcategorized into LUTD and bowel dysfunction.

BBD is prevalent. Almost 40% of referrals to pediatric urologists are related to LUTD, and 30% of referrals to pediatric gastroenterologists are related to bowel dysfunction. Up to 50% of patients seen at a pediatric urology clinic have combined LUTS and functional constipation (Burgers et al, 2013a, 2013b).

Patients with BBD represent a homogeneous group having more psychological difficulties, such as attention problems and oppositional behavior. These patients would potentially benefit from a multidisciplinary treatment approach involving urology, gastroenterology, and psychology professionals (Wolfe-Christensen et al, 2013).

CLINICAL ASSESSMENT OF LOWER URINARY TRACT CONDITIONS IN CHILDREN

The tools used for assessment of LUT conditions in children are given in **Box 136-1**. The assessment of children with LUT conditions should consist of a detailed and structured history, a frequency/volume chart, and a physical examination (Nevéus et al, 2006). Uroflowmetry and ultrasonography (US) can be added.

After screening the wet child by this means, those patients who will benefit from further urodynamic studies can be selected. Furthermore, patients with other conditions such as neuropathic bladder, structural anomalies of the LUT, or UTIs should be identified after this screening.

History

Medical History and Questionnaires and Scoring Systems

Literature on this topic is sparse. There are only some brief comments in the recent standardization reports of the ICCS (Nevéus et al, 2006; Austin et al, 2014). History taking in children with LUTDs should be detailed and structured. This should include relevant questions to exclude neurologic and congenital abnormalities. Bowel dysfunction can coexist in the form of encopresis, constipation, and fecal impaction and should be noted during obtaining the history. The urinary history should focus on symptoms related to both the storage and evacuation of urine. If possible, the history is obtained from both the child and the parents/guardians. Information from the child can then be checked and completed with parents' information. The majority of children with non-neuropathic LUTD typically present after toilet training with symptoms of either nighttime or daytime urinary incontinence, or both. Occasionally they can be recognized at an earlier age when the child presents for investigation of UTIs or vesicoureteral reflux (VUR).

Incontinence should be assessed after the standardization criteria of the ICCS. Clear distinction should be made between continuous and intermittent incontinence and between nighttime and daytime urine loss. Quantification of urine loss is subjective, and, if necessary, a pad test may help to make it more objective.

The medical history should start with an obstetric history asking for possible fetal distress, anoxia, birth trauma, prenatal hydronephrosis, and oligohydramnios. Developmental milestones should be evaluated. Any associated stool problems can raise suspicion for neurogenic impairment. Information on toilet training and ages at which continence was obtained during day and night can be useful to distinguish those children at risk for having developed LUTD. Early toilet training and early continence are sometimes considered risk factors for developing LUTD. Furthermore, voiding frequency, urine loss frequency, urge, and reactions to urge should be assessed. These data should be controlled by the data obtained from the voiding chart.

Toilet behavior and subjective quantification of the urinary stream are important parameters. Is urinary flow in one stream or interrupted? Staccato voiding is difficult to distinguish by the patient; however, fractionated voiding is well recognized. Does the child have to strain during voiding. How is the urinary stream? Especially in girls, one should ask for deviations of urinary stream or eventual compensations in toilet posture. Many girls with an anterior deflection of the urinary stream take a forward bent position on the toilet. Urge and reactions to urge should be assessed. Most parents will tell that their child waits too long to go to the toilet. Instead, however, it is the child's bladder that contracts too early. Some children hold urine while squatting, closing the urethra with the heel, the so-called Vincent's curtsy sign (Fig. 136-5).

Figure 136-5. Vincent's curtsy sign.

Previous UTIs and relevant surgery should be queried. Bowel function (obstipation, soiling) as well as menstrual and, if applicable, sexual function should be assessed. Familial history, which often is positive in pediatric LUTDs also should be included. General history taking includes questions relevant to neurologic and congenital abnormalities. All diagnostic and therapeutic interactions that have been performed previously should be assessed.

Scoring systems for pediatric incontinence are not popular among pediatric urologists, despite the fact that scoring systems in general provide a more standardized assessment of voiding pathologic conditions. Because LUTD became recognized as a clinical entity affecting many children, two scoring systems have been published. The first scoring system was used by the International Reflux Study in Children group and described by Jan van Gool and colleagues (1992). This scoring system, developed to interpret data obtained from the International Reflux Study, was not validated and has never been used in daily practice. A more recently published scoring system devised by Akbal and associates (2005) is based on this scoring system. A second scoring system, from the Toronto group, was published in 2000 (Farhat et al, 2000). It is a validated questionnaire consisting of 10 questions with good sensitivity and specificity for diagnosing dysfunctional voiding. The same group published a manuscript on the use of their scoring system to predict outcome of reflux after treatment of dysfunctional voiding (Upadhyay et al, 2003).

The main advantage of using a scoring system is to help people with limited experience. Practitioners that deal with children with LUTD on a daily basis often have the skills, learned through experience, to diagnose these conditions. For the less experienced, a scoring system can indicate that an LUTD might be present and that further investigations, such as a voiding diary and uroflowmetry, are needed. In addition to aiding diagnosis, a scoring system is a tool to measure LUTD during therapy, allowing comparison of the effectiveness of different therapies and thus helping provide the best therapy to our patients, based on evidence.

Recently questionnaires and scoring systems for BBD have been developed. They are found to be valid and reliable (Afshar et al, 2009; Drzewiecki et al, 2012). A validated bladder/bowel dysfunction questionnaire is a useful tool in the pediatric urology clinical

setting that correlates well with physician assessment. It can help patients and their families to better define their bladder/bowel symptoms before their visit; however, it should be noted that some families will not be able to fill out the questionnaire appropriately.

Frequency Volume Chart or Voiding Diary and Bowel Diary

The frequency/volume chart is a diary recording fluid intake and urine output over 24-hour periods. Episodes of urgency and urine loss also can be recorded. Urine loss is quantified by recording if clothing had to be changed after the urine loss (= important urine loss) or not. The chart gives information about fluid intake, number of voidings, voided volume, and urine loss. It can be used for diagnostic and therapeutic purposes (Olbing, 1992). For diagnostic purposes the chart should cover at least 3 days of registration. In therapy it is important that the child takes the responsibility to fill out the chart, because this enhances motivation and participation to training.

A lot of information can be obtained from these charts, as follows:

- Voiding frequency
- Total voided volume in 24 hours
- Average voided volume
- Largest and smallest voided volume
- Distribution of urine volume over day and night
- Urine loss
- Fluid intake

The close relationship between bladder and bowel function requires careful screening of the bowel function to rule out BBD. The recommended workup for bowel dysfunction in the context of BBD is outlined in the ICCS guideline on the management of functional constipation in children with LUT symptoms (LUTS) (Burgers et al, 2013b). Briefly, a 7-day bowel diary is advisable and includes the Bristol Stool Form Scale. The diagnosis of functional constipation in children is controversial, and the Rome-III criteria are the most commonly accepted guideline for diagnosis (Rasquin et al, 2006).

Physical Examination

Besides a general pediatric examination, which pays special attention to abdominal palpation looking for fecal impaction, perianal and perineal sensation, anal sphincter tone, and bulbocavernosus reflex should be assessed. The perineal region is supplied by the sacral segments S1 to S4, which also supply part of the bladder and the urethral sphincter.

Complete evaluation of the back with special attention for cutaneous manifestations of an underlying occult spinal dysraphism (lipoma, skin discoloration, hair growth) is necessary to rule out any underlying neurogenic cause (Mandell et al, 1980). Examination of lower extremities can show lesions compatible with neurogenic diseases affecting the lumbar cord. Muscle atrophy, foot deformities, and any asymmetry of the lower extremities must draw our attention. Genital examination, which comprises inspection of the introitus in girls with special attention to the position of the urethral meatus, appearance of the hymen, and inspection of the penis and the meatus urethrae in boys, should be done (Hoebeke et al, 1999).

Urinalysis and Other Laboratory Investigations

Urinalysis may provide information that could be missed by the clinical assessment. Asymptomatic bacteriuria is sometimes observed in the wet child. Infection can be the consequence of the dysfunctional voiding because turbulence in the urinary stream can milk-back bacteria from the urethra to the bladder. On the other hand, infection can be the origin of some irritative bladder symptoms. The presence of glucose or proteins in urine can detect metabolic or nephrologic diseases that can interfere with bladder function.

Ultrasonography

All children with LUTD should receive a screening ultrasound study. In most instances this should be the first-line investigation in children with non-neuropathic LUTD because it is a simple, readily available, and noninvasive tool that can provide information both on anatomic and functional problems when performed by experienced pediatric radiologists. Evaluation of the bladder after voiding can show the amount of residual urine.

Ultrasonography also has been used in the study of the pelvic floor musculature. In boys, the external sphincter, puborectalis, and bulbocavernosus have been observed on US to contract during a hold maneuver. In girls, lengthening of the urethra and movement of the bladder neck in the direction of the symphysis is seen. However, in patients with non-neuropathic bladder-sphincter dysfunction, approximately one third of the children were unable to elicit movement of the pelvic floor or had paradoxical movement. The clinical significance of this remains unclear, but when introduced to a period of urotherapy, marked improvement of symptoms had been reported. Similarly US has been employed in the study of bladder neck mobility. Studies have shown that in a proportion of girls with hyperlaxity of joints, coughing or straining would result in a wide opening of the bladder neck and urethra. In this group of girls, urotherapy would prove difficult and occasionally some would go on to require surgery to the bladder neck (de Jong et al, 2006, 2007).

More recently, US has been used to measure bladder parameters, including bladder wall thickness, and these can be used in calculating a bladder volume and wall thickness index (BVWI). This BVWI can be classified into normal, thick, or thin according to the measured parameters. **Bladder wall thickness measured by US has been correlated with LUTD with good specificity, and this can act as a reliable tool to guide for further invasive investigations (Yeung et al, 2004).** Furthermore, US can detect structural anomalies of the urinary tract. Upper tract dilation, which can signify VUR or obstruction either at the vesicoureteral or the ureteropelvic junction, can be detected. The advantage of US in children is that it is a completely noninvasive and nonpainful examination without risk for irradiation as in other imaging modalities.

Other Imaging Studies

Radiologic examination of the spine may be necessary to rule out any neurogenic causes of bladder-sphincter dysfunction. A voiding cystourethrogram may be performed in patients to rule out VUR. Information on bladder emptying efficiency may be obtained, and the status of the urethra can be assessed to exclude any outflow obstruction.

Urodynamic Studies

Urodynamic studies are employed to evaluate the physiologic parameters involved in the bladder mechanics during filling and voiding. Uroflowmetry, postvoid residual (PVR) urine, sphincter EMG, and 4-hour voiding observation are noninvasive tests and can be used as first-line investigative tools for LUT function. Detrusor activity, bladder sensation, bladder compliance and capacity, and urethral function during both the filling and the voiding phases of cystometry can be recorded during the urodynamic study (UDS) and then used as reference for classification of LUTD. Video-urodynamic study incorporating images during storage and the voiding phase can provide better insight of LUT function.

Uroflowmetry and Postvoid Residual

Uroflowmetry is indicated in toilet-trained children with LUTS and/or UTI (Fig. 136-6). Although there is no specific contraindication for these tests, they are usually not recommended in children with acute illness or active UTI. Before the tests, the uroflowmeter should be calibrated and the scale of interpretation sheet should be adjusted

Figure 136-6. Parameters in a bell-shaped uroflowmetry curve.

to a 1 : 1 ratio for flow rate (mL/sec) versus time (sec). The uroflowmeter should be placed in a quiet and private place that makes the child feel comfortable and relaxed. The child micturates at normal desire to void. Any artifact (sharp peak in flow curve with duration less than 2 seconds) should be corrected before interpreting the uroflowmetry results.

Expected Bladder Capacity and Optimal Bladder Capacity

The most relevant parameters for interpretation of uroflowmetry are voided volume, Qmax, and uroflow patterns. Because these parameters depend on bladder capacity (voided volume + PVR), ICCS defines expected bladder capacity (EBC) as $(\text{age in years} + 1) \times 30 \text{ mL}$, which is useful for comparisons among children of variable ages. Voided volume of less than 50 mL is regarded as irrelevant for interpretation (Norgaard et al, 1998), whereas bladder capacity greater than 115% EBC or voided volume above 100% EBC are associated with frequent abnormal uroflow patterns and elevated PVRs (Yang and Chang, 2008; Chang et al, 2011). Thus optimal bladder capacity—that is, bladder capacity between 50% and 115% of EBC—is recommended as adequate for interpretation (Yang et al, 2003; Hoebeke et al, 2010). If abnormal parameters occur in the situation of bladder overdistention, uroflowmetry should be repeated.

Peak Flow Rate

Peak flow rate (Qmax) is defined as the maximal flow rate during voiding with duration of more than 2 seconds. Qmax is regarded by the ICCS as the most relevant variable when assessing the status of bladder outflow resistance (Nevés et al, 2006). Several nomograms for Qmax are published in the literature (Yang and Chang, 2012; Gupta et al, 2013; Yang et al, 2014). Yang and colleagues used the ranking method to construct a Qmax nomogram (Fig. 136-7). Minimally acceptable Qmax, approximately the 5th to 10th percentile of the nomogram, is defined as 11.5 mL/sec in children 4 to 6 years of age and 15.0 mL/sec in children 7 to 12 years (Yang and Chang, 2012; Yang et al, 2014).

Uroflow Patterns

Under some conditions, detrusor contractility in children is so good that it can overcome bladder outlet resistance, which makes Qmax less reliable in the evaluation of bladder outlet resistance. Therefore some consider uroflow pattern to be a more important parameter than Qmax. The uroflow pattern may provide a clue to the possible underlying cause of LUTD in children. The ICCS suggests that uroflow patterns could be classified as bell-shaped, interrupted, staccato, tower, and plateau types. Only the bell-shaped curve is regarded as normal. Interrupted flow (Fig. 136-8A) is defined as flow rate that reached zero during voiding, which may imply

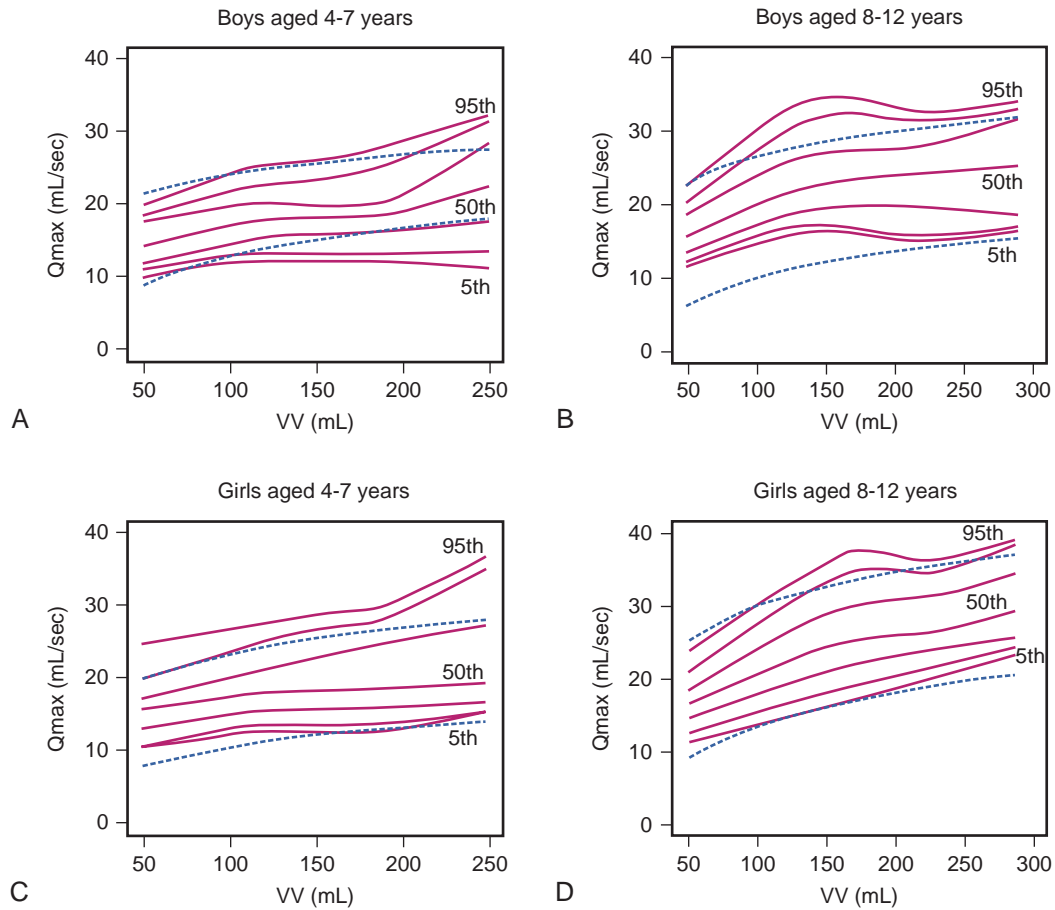

Figure 136-7. A-D, Peak flow rate nomograms (the lines of percentiles were 5th, 10th, 25th, 50th, 75th, 90th, and 95th percentiles, respectively, from the bottom up) in boys and girls aged 4 to 7 and 8 to 12 years. The 5th and 95th percentile line of the Miskolc nomogram (*dashed lines*) were plotted on the figures for comparison. VV, voided volume.

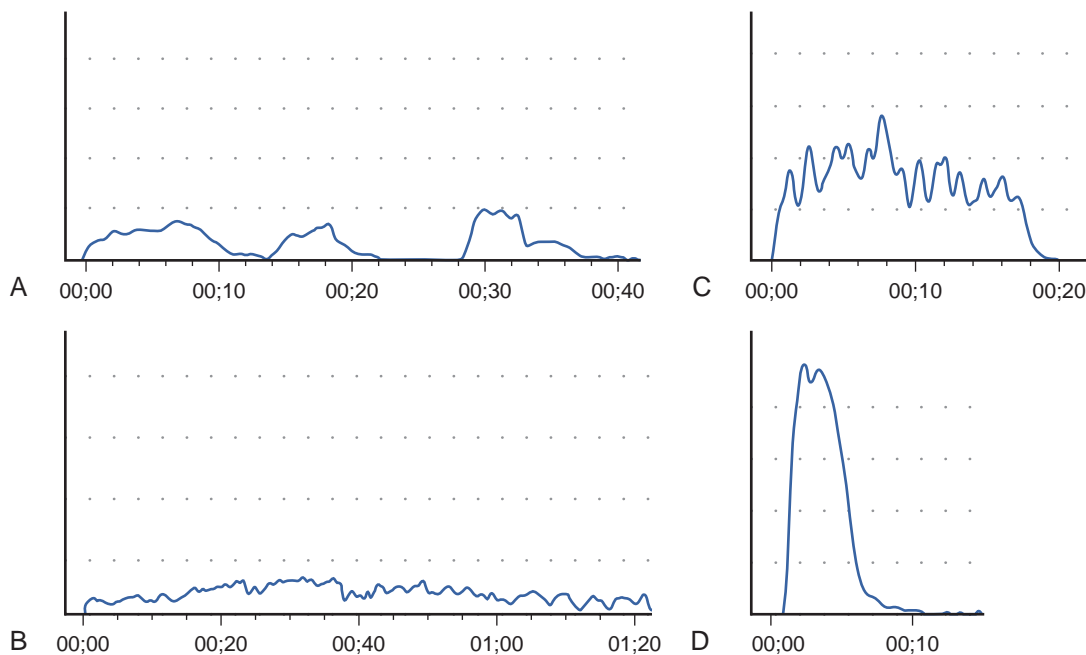

Figure 136-8. Patterns of uroflowmetry curves. A, Interrupted curve. B, Plateau curve. C, Staccato curve. D, Tower curve.

Figure 136-9. A uroflow pattern in a 12-year-old boy with anterior urethral valve fits criteria of both staccato and plateau patterns.

detrusor underactivity or pelvic flow overactivity during voiding. Plateau curve (Fig. 136-8B) is defined as continuous, low-amplitude, and flattened flow. Peak flow rate less than the age-specific minimally acceptable Qmax and lasting for 4 seconds could be two useful parameters to define plateau curve, which implies bladder outlet mechanical obstruction or tonic sphincter contraction. Staccato flow pattern (Fig. 136-8C) is defined as an irregular and fluctuated flow curve, and the fluctuations between peak and trough should be larger than the square root of Qmax. The cause of the staccato flow curve is assumed to be sphincter overactivity. The tower-shaped curve (Fig. 136-8D) is defined as sudden and high-amplitude flow, which is suggestive of detrusor overactivity. Time to peak flow rate is usually less than 2 seconds, and the left arm of the uroflowmetry curve is almost perpendicular to the x-axis. Peak flow rate more than age-specific 95th percentile of Qmax nomogram may be regarded as high amplitude.

In healthy children, the proportion of non-bell-shaped curves ranges widely from 2.8% to 37%, whereas only 3.8% of healthy children had repetitive non-bell-shaped curves, which can be defined as abnormal (Mattsson and Spangberg, 1994; Bower et al, 2004; Yang and Chang, 2008; Yang et al, 2014). Because subjective uroflowmetry patterning is liable to personal bias (Kanematsu et al, 2010) and substantial interobserver disagreement existed in classifying specific abnormal patterns (Chang and Yang, 2008), arguing that a specific type of abnormal flow pattern is present may be not clinically relevant. In addition, some abnormal uroflow patterns may fit criteria in two types of flow patterns (Fig. 136-9). Simply classifying uroflow pattern into normal and abnormal may be sufficient for clinical practice (Yang and Chang, 2012). Uroflowmetry should be repeated in cases with any abnormal flow pattern, with invasive UDS reserved for cases with repeated abnormal flow patterns.

Electromyography during Uroflowmetry

The use of EMG during pediatric uroflowmetry is controversial. EMG may help diagnose detrusor and sphincter/pelvic floor dys-synergy in cases with a staccato or interrupted uroflow pattern (Wenske et al, 2012). However, the perianal surface EMG may be compromised by artifact and may not really reflect urinary sphincter activity.

Postvoid Residual

PVR should be checked with transabdominal US within 5 minutes after voiding. Although urethral catheterization may be more accurate, possible complications of UTI and associated discomfort prevent its wide acceptability as screening tests. Until recently, first PVR nomograms were generated from 1128 children (Chang et al, 2013) (Fig. 136-10). For children 4 to 6 years of age, a single PVR greater than 30 mL or greater than 21% of bladder capacity, or

repetitive PVR above 20 mL or greater than 10% of bladder capacity can be regarded as elevated. For children 7 to 12 years, a single PVR greater than 20 mL or 15% of bladder capacity or repetitive PVR greater than 10 mL or 6% of bladder capacity can be defined as elevated (Chang et al, 2013; Austin et al, 2014). Because of the high variability of PVR tests, repetitive testing for PVR is warranted when the first PVR is high (Chang and Yang, 2009). The nomograms serve as a reference value for clinical practice; there is no existing clear cutoff point of PVR that is at higher risk for UTIs.

Four-Hour Voiding Observation

Four-hour voiding observation is a validated technique used for the evaluation of LUT function in infancy and pre-toilet-trained children. The method involves continuous observation of the freely moving infant with frequent ultrasound measurement of bladder filling and residual urine after each voiding. Voided volumes also may be measured by the weighing of diapers (Austin et al, 2014). This observation identified infants with LUTD, which affected the treatment outcomes of UTI and VUR (Sillen et al, 2010).

Conventional Fill Urodynamic Studies

This involves more sophisticated instruments and becomes more invasive to the patient, requiring a bladder catheter introduced transurethral or suprapubically. The use of suprapubic catheterization has been suggested as a better alternative to transurethral catheterization. Although it may be considered more invasive, it is much more physiologic than to try to void with a catheter in the urethra, particularly in young children. Not only is it obstructive to flow, but the trauma of placing the catheter just before the investigation may cause significant discomfort. For suprapubic catheterization, a 6-Fr double-lumen catheter is placed suprapubically under sedation and left in situ for 24 hours before commencement of the UDS.

The suprapubic catheter is connected to a computer system and used to measure intravesical pressure. Another catheter is placed in the rectum to measure intra-abdominal pressure surrounding the bladder. By subtracting the latter from the intravesical pressure, the detrusor pressure can be calculated. Sphincteric activity also can be measured with simultaneous perineal EMG recordings. All the measured data are directly fed into a computer for analysis and display of graphical measurements. The UDS looks at both the filling and voiding phases of the bladder. Bladder filling and storage are described according to bladder sensation, detrusor activity, bladder compliance, and bladder capacity. Pressure flow studies are carried out during the voiding phase (Fig. 136-11).

Traditionally, the bladder is filled artificially with normal saline at a rate of 10% EBC per minute to speed up the procedure. The child is asked to indicate his or her desire to void (if old enough to do so) and then void into a specially designed seat with a uroflowmeter attached. The investigator observing the study also should

Figure 136-10. Postvoid residual (PVR) nomogram is constructed by using the lower value of two consecutive tests: PVR in milliliter (A and B) and PVR in percent of bladder capacity (BC), (C and D) over varied age and BC/expected bladder capacity (EBC). The lines of 50th, 75th, 90th, and 95th percentiles were plotted separately in the nomograms.

make note of any events occurring during the study (e.g., any large movements of the patient, coughing, or in particular any urinary dribbling).

Video-Urodynamic Study. By combining cystometry with fluoroscopy, video-urodynamics can be performed, capturing fluoroscopic images of the bladder, bladder neck, and urethra (Fig. 136-12). Conventional fill urodynamics is performed in the usual manner with the child sitting in a specially designed chair with a uroflowmetry device in the fluoroscopy suite. Fluoroscopic images are taken during filling and voiding. This has the added advantage of being able to observe the shape of the bladder during filling and voiding, observing for signs of VUR, as well as the configuration of the urethra and pelvic floor. In institutes where video-urodynamics is not available, conventional urodynamics plus voiding cystography can be an alternative for video-urodynamics.

Natural Fill Urodynamic Studies

More recently, studies have shown that the nonphysiologic filling of the bladder during conventional urodynamics, even at low filling rates, can lead to misrepresentations of true bladder activity during normal situations. Therefore natural filling urodynamic studies may be performed in which the child is asked to drink to allow the bladder to fill at its own rate. Urodynamic studies in children with an overactive bladder usually reveal detrusor overactivity associated with a small bladder capacity but occasionally may be normal, with incontinence only barely perceptible, particularly if conventional cystometry rather than natural filling cystometry is used. It appears that the artificial filling may inhibit the detrusor response and attenuate its maximum contractile potential, rendering detrusor instability much less pronounced and undetectable. Therefore natural filling cystometry is the preferred technique in children; better still, the combined use of artificial and natural filling urodynamic studies

is helpful to accurately delineate the underlying bladder dysfunction (Yeung et al, 1995a, 2010).

Ambulatory Urodynamic Studies

The unfamiliar hospital and urodynamic laboratory environment, as well as the presence of a urodynamics investigator, can sometimes cause significant distress, particularly to young children. To overcome this, an ambulatory UDS (AUDS) may be performed. The major advantages of AUDS were in natural filling of the urinary bladder; therefore this can be applied in children who are refractory to standard urotherapy and cannot tolerate a conventional UDS or with noncontributory results with conventional UDS. However, the labor-intensive and time-consuming nature of AUDS prevented its widespread use in children. Additionally, some children still suffered from distress and discomfort and were unable to void because of AUDS (Deshpande et al, 2012).

The AUDS system converts digital pressure signals through modulated infrared wave or Bluetooth (Luna [Nokia], MMS). The evaluation time varied from 45 minutes to 24 hours. During the investigation the infant or child can conduct normal activities, be totally mobile, and be accompanied by one or both of the parents undisturbed in a private place. A diary including activities, urinary dribbling, incontinence, urgency, and micturition should be recorded continuously. Overall, it allows for a continuous monitoring of bladder function under near-natural conditions for the child. For toilet-trained children, uroflowmetry may be performed with a uroflowmeter.

Limited studies have been undertaken with a small number of children enrolled. Care should be taken during interpretation of AUDS results. AUDS can yield more detrusor contractions, lower voided volume, and greater voiding pressure than conventional UDS (Yeung et al, 1995a; Deshpande et al, 2012). High end-filling

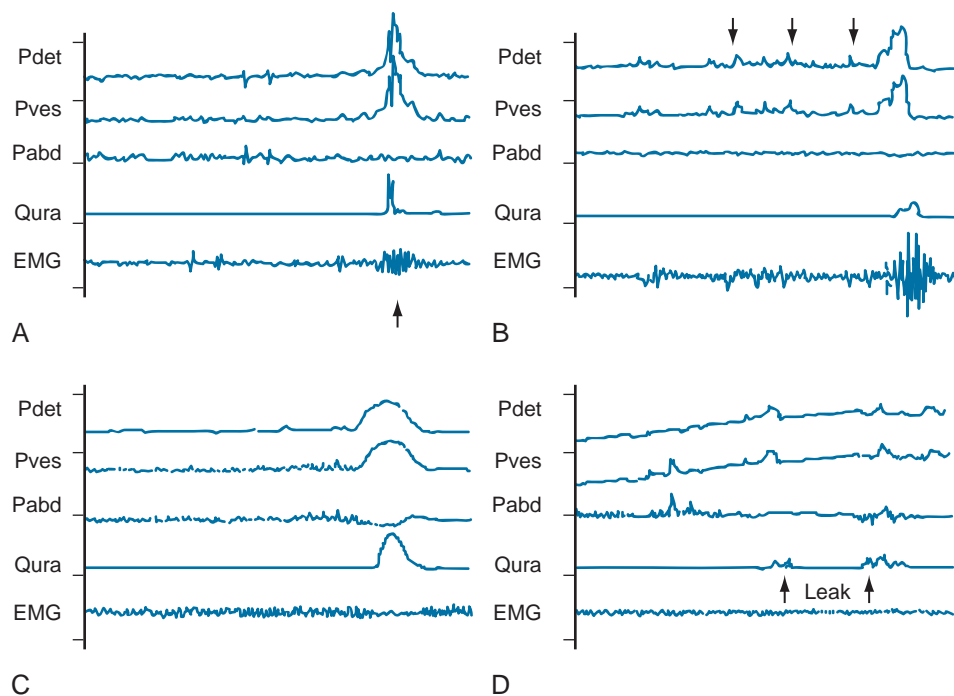

Figure 136-11. Various bladder functional patterns. A, Dyssynergic patterns with an increase in sphincteric electromyographic activities during micturition (arrow), leading to an interrupted urinary flow. B, Overactive bladder, characterized by frequent unstable detrusor contractions (arrows) during the filling phase. C, Normal female micturition pattern; note the pelvic floor relaxation as evidenced by a drop in abdominal pressure during micturition. D, Bladder with low (poor) compliance as evidenced by a rapid increase in intravesical pressure during filling, often associated with urinary leakage (arrows). EMG, electromyogram; Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, intravesical pressure; Qura, uroflow. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Saunders; 2010. p. 353–65.)

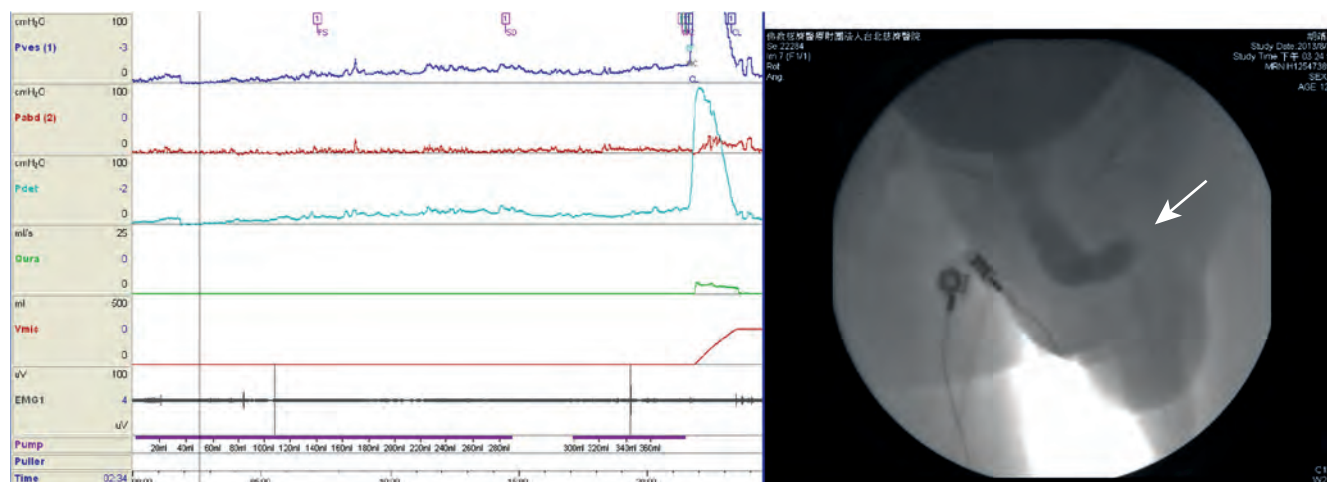

Figure 136-12. Video-urodynamic study in a 13-year-old boy with overactive bladder and bilateral hydronephrosis. High detrusor pressure with low uroflow rate is shown in the pressure flow study, and simultaneous image depicts stenosis at the level just distal to bulbar urethra (arrow) with proximal dilatation.

KEY POINTS

- LUT function in young children is very different from that in adults. Infants void with significantly higher maximum detrusor pressures than in normal adults, and male infants void with significantly higher pressures than females.
- The high detrusor pressures during micturition were mainly observed only during the first year of life and decreased progressively with age. They most probably represent variations between individual infants in the maturation process of detrusor and sphincter coordination during the first 1 to 2 years of life.
- During the first 2 to 3 years of life there is progressive development from an initially indiscriminate infantile voiding pattern to a more socially conscious and voluntary or adult type of micturition.
- Micturition control is achieved through an active learning process whereby the child acquires the ability to voluntarily inhibit or initiate voiding at socially convenient times.
- The natural evolution of bladder control entails an intact nervous system and depends on at least three main events occurring in parallel: (1) a progressive increase in bladder functional storage capacity; (2) maturation of voluntary control over the urethral striated muscle sphincter; and, perhaps most importantly, (3) development of direct volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit the micturition reflex.
- LUTS and LUTDs are best classified according to their relation to the storage and/or emptying phase of bladder function
- It is now well recognized that LUTD often has associated bowel dysfunction, and together this is known as BBD.
- BBD is prevalent. Almost 40% of referrals to pediatric urologists are related to LUTD.
- VUR may be secondary to underlying LUTD, particularly in girls.
- An adequate history should include congenital abnormalities, voiding and wetting patterns (including a voiding diary), and assessment of bowel function. Structured questionnaires can be useful.
- Abnormalities of the lower spine should be sought specifically to exclude the possibility of an occult spinal dysraphism.
- Ultrasonography is useful to assess bladder function and wall thickness, as well as pelvic floor function.
- Normal uroflow pattern is bell shaped. Age- and gender-specific peak flow rate and PVR can be helpful in detecting pediatric LUTD.
- UDS looks at both the filling and voiding phases of the bladder.
- Artificial filling may inhibit the detrusor response and attenuate its maximum contractile potential, rendering detrusor instability much less pronounced and undetectable.

pressure during conventional UDS was not observed in AUDS. In addition, the artifacts can make interpretation more difficult. The standard AUDS procedures and reference parameters generated from ambulatory UDS need more investigation. With the advance in technology, hopefully, we may evaluate the urinary bladder in children in a more natural way.

SUMMARY

Despite extensive clinical and animal research, it is perhaps embarrassing to admit that the exact neurologic mechanisms of the development of micturition control from newborn to infancy and later childhood, as well as the pathophysiologic pathways that are involved in various types of LUTD, have as yet remained largely unclear. However, it is clear that the bladder and the brain are in constant communication from as early as in utero, and there are extremely rapid and extensive changes and modulation of micturition reflexes during the early postnatal period, leading to abundant potential for developmental errors and voiding dysfunctions. Over the last decade we have learned that both normal and abnormal LUT function is much more dynamic than we had previously believed. New investigative tools and research have allowed us to study in much greater detail and precision the various components, including neurologic, muscular, urodynamic, and hormonal mechanisms, that may intricately interact to produce different patterns of LUTDs, and their relentless, dynamic changes.

Vesicoureteral reflux (VUR) represents the retrograde flow of urine from the bladder to the upper urinary tract. VUR is a common clinical entity. Its clinical challenges arise from the fact that it is usually asymptomatic. When it is not, however, it is responsible for pyelonephritic scarring and can be associated with congenital renal dysmorphism. There are many unresolved issues regarding the cause, diagnosis, and management of VUR. This chapter attempts to reconcile some of these areas by interpreting the best available information in the literature. Some areas, however, continue to await more rigorous study. Some may remain unresolved for quite some time.

HISTORICAL PERSPECTIVE

VUR has a unique distinction of having evolved from an anatomic curiosity around the 1st century AD into one of the most contentious and complex areas of urology today. Galen and da Vinci made the first references to VUR by Western medicine when they alluded to the ureterovesical junction (UVJ) as a mediator of unidirectional flow of urine from the kidneys to the bladder. Although VUR was first demonstrated to be a normal finding in dogs and rabbits (Semblinow, 1907), it was a gynecologic misadventure that revealed that VUR in human adults may not be a normal state (Pozzi, 1893). Sampson, in 1907, suggested that the oblique course of the ureter through the bladder wall created a locking mechanism at the UVJ and also was the first to imply that VUR might lead to renal

infection (Sampson, 1903). Although it was not possible to uniformly demonstrate VUR in all people in cadaveric studies (Young, 1898), it was not until the UVJ had been more clearly dissected that it was realized the incidence of VUR varied with the length of the ureter's obliquity in the bladder and the formation of the trigone (Gruber, 1929).

Pivotal discoveries occurred when Hutch (1952) reported on a relationship between VUR and chronic pyelonephritis in paraplegic patients and Hodson (1959) observed that urinary tract infection (UTI) and renal scarring carried a high likelihood of VUR in children.

Two seminal bodies of work defined the modern era of VUR. The first, the work of Ransley and Risdon (1979), defined the pathophysiology of reflux nephropathy by demonstrating the relationship among infection, reflux, and pyelonephritic scarring. Second, these observations complemented the clinical studies of Smellie (1991) and colleagues, who galvanized the related concepts inherent in clinical UTI, bacterial pyelonephritis, renal scarring, and VUR. In 1985 a consensus system for the grading of reflux was published by Lebowitz and colleagues (1985) on the basis of the International Reflux Study Group's deliberations.

Until recently, the virtues of medical therapy to avert infections and surgical therapy to correct reflux have been evenly debated for more than 20 years. However, the recent introduction of the biodegradable cross-linked polysaccharide dextranomer and stabilized hyaluronic acid for use in injectable endoscopic correction of reflux, as well as re-examination of the basis for medical therapy and the

risks for reflux, have initiated a re-examination of virtually all aspects of reflux. From the age-related impact of reflux, through use of antibiotics for medical prophylaxis, invasiveness of cystography, and traditional indications for surgery, the impact of reflux and its management are being openly explored. Although the fundamental biologic importance of reflux disease is not in question, many facets of how reflux diagnosis and management are approached may take new shape in the coming decade.

DEMOGRAPHICS

Prevalence

The tendency for VUR to resolve spontaneously on the one hand or persist beyond its natural resolution rate because of abnormal bladder dynamics makes it difficult to confidently generalize the true prevalence of reflux from a given population. In one meta-analysis of studies of children undergoing cystography for various indications (Sargent, 2000), the prevalence of reflux was estimated to be approximately 30% for children with UTI and 17% without infection. **In contrast, reflux may be present in up to 70% of infants who present with UTI (Baker et al, 1966).** In a population of 157 adults investigated for incidental hypertension without any evidence of renal abnormality, the prevalence of VUR was estimated to be 19%, with high-grade reflux in more than half of the refluxing group (Barai et al, 2004). Reflux is relatively uncommon in adult men (Chapple et al, 1990). In asymptomatic infants followed for antenatal hydronephrosis, the prevalence of reflux ranges from 15% in infants with absent or mild hydronephrosis on postnatal ultrasonography (Phan et al, 2003) to 38% in a group of neonates with various postnatal upper tract sonographic anomalies, including hydronephrosis, renal cysts, or renal agenesis (Zerin et al, 1993).

Gender

Differences in reflux rates between males and females may suggest a sexual dichotomy in the function of the lower urinary tract, bladder outlet, and urethra. In one study of 117 infants assessed for reflux after fetal upper tract dilation, 76% of refluxing infants were male (Ring et al, 1993). In later life, the likelihood of having reflux if presenting with a UTI is higher if male than female (Shopfner, 1970), even though the great majority (85%) of prevailing reflux in older children is in females. A confounding factor in understanding true gender differences in reflux between males and females is the gender-driven predisposition to UTI. Uncircumcised male infants show a 12-fold greater risk for UTI than circumcised males, as well as a greater propensity for harboring periurethral uropathogenic flora (Wiswell et al, 1988; Wiswell and Hachey, 1993). The greater incidence of UTI will necessarily invite more frequent evaluation and therefore detection of VUR in this population. It is not known whether the incidence of reflux detection would rise in females if they were to be incidentally evaluated for reflux as often as infant males. In a related finding, only 10% of patients entered into the International Reflux Study in Children from the United States were boys compared with 24% entered from Europe. The circumcision rate in the latter group was only 5% compared with 62% in the U.S. group ($P < .001$) (Weiss et al, 1992b).

Reflux in the Fetus

Most studies of fetal reflux do not in fact detect reflux per se in the fetus but relate fetal hydronephrosis parameters to reflux in the neonatal period. However, fetal hydronephrosis is common, often resolves, and has low specificity for postnatal VUR. Nevertheless, fetal hydronephrosis is commonly associated with postnatally detected reflux. Zerin and associates (1993) described a 38% detection rate of reflux in 130 neonates with prenatal hydronephrosis. In 19% the reflux was bilateral. It is suggested that the lower the threshold for defining hydronephrosis (in millimeters of pelvic diameter) in the fetus, the more often reflux will be detected postnatally (Anderson et al, 1997). This leads to speculation as to

TABLE 137-1 Incidence of Reflux in Patients with Urinary Tract Infections

AGE (yr)	INCIDENCE (%)
<1	70
4	25
12	15
Adults	5.2

From Baker R, Maxted W, Maylath J, et al. Relation of age, sex, and infection to reflux: data indicating high spontaneous cure rate in pediatric patients. *J Urol* 1966;95:27.

whether reflux is a normal variant in the population but becomes clinically relevant only in some because of a predisposition to UTI, a conclusion supported by the observation that reflux without infection is of questionable clinical significance. Boys appear to harbor postnatal reflux more commonly—a 6:1 male-to-female ratio was reported in one study of 27 cases (Marra et al, 1994). The highest grades of reflux are most commonly associated with renal scintigraphic abnormalities. In many cases, even in the absence of any infection history from birth, the presence of a small kidney with globally reduced scintigraphic function may indicate that such renal scintigraphic abnormalities may be associated with a developmental ureteric bud abnormality associated with high-grade reflux or secondary to the reflux itself (Oliveira et al, 1998; Stock et al, 1998).

Age

As stated previously, because the natural history of reflux involves spontaneous resolution over time, it is self-evident that less primary reflux would be prevalent in older children compared with infants (Table 137-1). Even in the presence of infection or asymptomatic bacteriuria, reflux is more common in younger patients (Smellie, 1991).

Race

Little is known about racial predisposition to reflux worldwide because reflux studies have generally been restricted to Western countries. **One difference established over several studies is the relative 10-fold lower frequency of reflux in female children of African descent (Skoog and Belman, 1991; Chand et al, 2003).** In addition, reflux resolved sooner in this population ($P < .005$). In a series of non-Caucasian children with a 4:1 male-to-female ratio, 58% of whom were younger than 1 year of age presenting with UTI (72%), voiding difficulties (10%), or other malformations (14%), reflux was present in only 10% (West and Venugopal, 1993). Even in follow-up of antenatal hydronephrosis, reflux was found in 17.6% of 51 nonblack versus 0% of 58 black infants (Horowitz et al, 1999). Such differences may involve a delay in maturation of the antireflux mechanism in Caucasian patients as the race-associated frequency of reflux becomes equal regardless of race after 10 years of age (Melhem and Harpen, 1997).

KEY POINTS: DEMOGRAPHICS

- The younger the child with UTI, the greater is the likelihood of discovering reflux.
- VUR is relatively rare in children of African descent.

INHERITANCE AND GENETICS

Sibling Reflux

A recent meta-analysis of sibling reflux studies suggests the prevalence of VUR in siblings to be approximately 32% (Hollowell and Greenfield, 2002). However, the prevalence may be as low as 7% in

older siblings (Connolly et al, 1996) or as high as 100% in identical twin siblings (Kaefer et al, 2000). **The latter finding undeniably supports the notion that VUR can be an inherited condition** and that the genetic mode of transmission may in some cases be autosomal dominant. Although a heightened prevalence of reflux exists in siblings of refluxing index patients, the natural history of reflux would suggest that siblings who are older harbor reflux less often compared with relatively younger siblings because of spontaneous reflux resolution (Connolly et al, 1996). However, none of the existing sibling studies rigorously state whether the prevalence of sibling reflux depends on whether the sibling is younger or older than the index patient. By virtue of its detection by screening, sibling reflux is usually asymptomatic at the time of diagnosis. Furthermore, the tendency for reflux to have resolved before any renal changes such as focal scarring detected by imaging can be reliably ascribed to the reflux itself further complicates the management of reflux in siblings. These clinical features underscore the difficulties inherent in formulating meaningful recommendations for the management of sibling reflux detected by screening.

Much of the concern for sibling reflux detected by screening stems from reports of renal abnormalities detected by ultrasonography or nuclear scintigraphy in these patients.

In one retrospective study of 123 screened siblings, 44 (36%) demonstrated VUR on voiding cystography (Houle et al, 2004). Of these patients, 37 underwent renal imaging. Ultrasonography was abnormal in 30% and renal scintigraphy, when used, was abnormal in 28%. However, in siblings older than 2 years, renal scintigraphic abnormalities were twice as common as in the entire group of siblings. The authors concluded that renal damage is therefore progressive in the older siblings and proposed earlier screening of siblings of refluxing index patients. However, this study fails to address the fact that renal damage or aberrant formation may have occurred very early and over time (beyond 2 years of age), renal growth may have exaggerated the appearance of such scintigraphic abnormalities. Scintigraphic results may become exaggerated by normal cortical growth surrounding a scarred region that has failed to grow or by compensatory hypertrophy of a contralateral kidney. **The missing link is a prospective scintigraphic or sonographic follow-up of asymptomatic refluxing infant sibling children from birth onward.** Finally, the reporting of scintigraphic results by many sibling reflux studies is confounded by failing to differentiate between aberrant renal development often associated with higher grades of reflux and true scarring secondary to infection and inflammation. Moreover, the ability to modulate the course of the processes that mediate congenital dysplasia is not possible presently, as it is with scarring. In the absence of such data and faced with the invasive nature of the gold standard test for reflux, the cystogram, one is left with the following questions.

Is asymptomatic reflux in a sibling of clinical concern? If the propensity for UTI, with or without VUR, could be reliably determined to be genetically regulated, it would strengthen the case for screening for reflux in a sibling. Because biologic infection propensity cannot be presently determined in either an index patient or his or her sibling, the likelihood of developing a UTI cannot be used to support screening siblings for reflux. Therefore the aggregate clinical information available must be relied on for the sibling in question. **Because it is renal consequences of reflux that are at issue, rather than reflux itself, siblings may be better served by noninvasively screening for cortical abnormalities first, and screening for reflux if history of compounding factors such as UTI or bowel and bladder dysfunction are manifested.** The intensity of renal assessment, using ultrasonography for general screening or a nuclear scan for highest accuracy, could then be tempered by clinical factors, including family history, patient and family compliance with follow-up, blood pressure, a history of UTIs and fevers, and voiding dysfunction. The absence of renal imaging abnormalities would allow the clinician to conclude that reflux, if present, has not yet been of any renal structural consequence.

Should screening depend on sibling age? Because the risk for new renal scarring after pyelonephritis is lower in children older than 5 years of age, older siblings would likely suffer fewer conse-

quences from a recent reflux-induced pyelonephritis and therefore stand to benefit less from confirming a diagnosis of reflux and instituting antibiotic prophylaxis than an infant or younger sibling. Nevertheless, a history of untreated febrile infections would support a decision to consider renal assessment or even obtain a cystogram in an older sibling.

Thus, by imaging the kidneys first, followed by assessing the integrity of the UVJs, a rational top-down approach to sibling reflux screening emerges. Such an approach helps strike a balance between the invasive nature of reflux detection and classic commitment to prophylaxis versus first detecting existing renal cortical abnormalities that might be the result of past or ongoing reflux. If consideration of age and renal integrity is combined, a possible graded approach to screening can be developed for siblings older or younger than 5 years of age, with or without renal structural abnormalities. The proximate urologic and voiding history also must play a deciding role in whether a sibling is ultimately screened by cystography for VUR. Thus, in siblings 5 years or older with normal kidneys, little would be gained from detecting reflux that could not be addressed by responding to a febrile UTI in the usual fashion as for the general pediatric population. Indeed, the knowledge that the index patient has VUR might heighten the attention to family or self-reporting regarding urinary symptoms in the older sibling. In siblings 5 years or older with renal abnormalities, the suggestion would be of past or continuing reflux. Ruling the diagnosis in or out by cystography could then depend on prevailing voiding habits and proximate urologic history. The sibling younger than 5 years of age with normal kidneys would be managed on the basis of clinical judgment regarding likelihood for infection rather than an immediate need to diagnose reflux. The sibling younger than 5 years with cortical renal defects would have the most to lose by a febrile infection in the face of reflux and the attendant risk for additional cortical loss after reflux-induced pyelonephritis triggered by an infection (Hunziker et al, 2014). In this case, aggregate knowledge of the potentially higher prevalence of reflux in siblings combined with a fever history, either unexplained or with UTI, or significant bowel dysfunction would support select consideration of cystography. In any sibling, if reflux is diagnosed, the indications for reflux correction remain the same as for the general refluxing pediatric population.

Genes Involved

In addition to sibling reflux, a prospective screen of progeny of patients with reflux revealed a 66% rate of reflux in the offspring (Noe et al, 1992), which further strengthens the notion of an autosomal dominant component to the genetic mechanism of reflux. The substantially higher rate of reflux in siblings and progeny of index patients than in the general population defines these patients as susceptible to renal morbidity. Previous segregation and linkage analyses have implicated a number of loci in the pathogenesis of VUR, though no specific gene product or functional role for these loci in reflux has yet been identified (Chapman et al, 1985; Feather et al, 2000). Several studies used a morphogenetic approach to search for candidate genes that may underlie VUR. The original ureteric budding studies of Mackie and Stephens (1975), which correlate the position of ureteric budding from the mesonephric (wolffian) duct with that of the final ureteric orifice, provide a modern basis for a genetic interpretation of VUR. Several genes have been observed to regulate these developmental processes and, by extension, are believed to serve as potential regulators of UVJ integrity, though their specific connection to VUR is clinically unproved. Indeed, genetic misregulation of ureteric budding is believed to underlie many congenital anomalies of the kidney and urinary tract (often referred to as CAKUT) (Miyazaki and Ichikawa, 2003). *Pax2* is a transcription factor regulating kidney, central nervous system, and ocular development in mice. It is necessary for ureteric budding in mice (Keller et al, 1994). *PAX2* is located on human chromosome 10q, and mutations have been reported in human syndromes involving colobomas and renal anomalies, including hypoplasia, dysplasia, glomerulonephritis, and VUR (Sanyanusin et al, 1995). However, *PAX2* has not been shown to be a major determinant of

primary VUR (Choi et al, 1998; Cunliffe et al, 1998). Glial-derived neurotrophic factor (*Gdnf*) and its receptor *RET* show strong involvement in UVJ formation in mice (Yu et al, 2004). Overexpression of *RET* in mice leads to abnormal placement of the ureteric bud and is associated with a 30% incidence of VUR at birth compared with 4% in wild-type mice. Nevertheless, the *Gdnf*-*Ret* signaling complex has been found to not mediate VUR in humans (Shefelbine et al, 1998). One reason for the conflicting studies in the literature on reflux genetics is that clusters of specific populations with their own inherent genetic backgrounds occasionally amplify a putative gene association for VUR that does not apply to all populations. This was recently reported for *RET*, which showed a very high-frequency *RET* polymorphism in patients with primary VUR from Quebec, Canada, but not in a similar cohort of patients with primary VUR from Ireland (Darlow, 2009). Another fascinating animal model of VUR is observed after deletion of the uroplakin III gene (Hu et al, 2000). However, no structural uroplakin III gene alterations have been noted in human cohorts with VUR (Giltay et al, 2004; Jiang et al, 2004). One explanation for this finding may be that major uroplakin mutations are developmentally lethal in humans. Finally, members of the renin-angiotensin family of proteins have been implicated in several renal and ureteral developmental anomalies, including uteroperic junction obstruction (UPIO) and megaureter (Hohenfellner et al, 1999). Although associations between angiotensin receptor-2 (*Agtr2*) (Yoneda et al, 2002) and angiotensin-converting enzyme (*ACE*) (Liu et al, 2004) genes with VUR have been sought, no definitive etiologic link with VUR has been found. Similarly, a more recent study of specific insertion/deletion polymorphisms of *ACE* in children with and without renal scarring failed to confirm a previously suspected association between homozygous *ACE* deletion polymorphism and scarring, even when stratified for age or VUR (Sekerli et al, 2009). Notwithstanding an observed pattern of autosomal dominant inheritance in some families, the failure to identify any strong genetic mechanism in primary VUR in humans despite the presence of convincing animal genetic models of reflux argues for a more complex polygenetic mechanism of disease in humans. Indeed, in the largest whole-genome linkage and association scan for primary nonsyndromic reflux done to date, no clear overlap involving previously reported gene candidates was found (Cordell, 2010). Specifically, this study did not detect any association with *AGTR2*, *HNF1B*, *PAX2*, *RET*, *ROBO2*, or uroplakin III. The authors concluded that major gene loci may not exist for common VUR in the populations tested.

KEY POINTS: SCREENING, INHERITANCE, AND GENETICS

- The prevalence of reflux is higher in siblings.
- There is a tendency for an autosomal dominant pattern of inheritance.
- Probably many genes are involved.
- It cannot be assumed that all cortical abnormalities in refluxing siblings are acquired. The lack of prospective studies should temper the notion of mass screening of siblings.

EMBRYOLOGY OF THE URETEROVESICAL JUNCTION

A full discussion of the embryology of the trigone and ureteric orifice is found elsewhere in the text. In brief, two events proceed simultaneously to govern the ultimate position and integrity of the UVJ. At one point, the embryonic ureter buds from the mesonephric or wolffian duct to define the metanephric duct or early fetal ureter. The wolffian duct (early vas deferens) and early ureter can be thought of as forming the two upper arms of a Y with the distal mesonephric duct as the stem of the Y. While budding is occurring, the distal mesonephric duct is being drawn and incorporated into the region of the urogenital sinus (UGS), which later becomes the bladder. Incorporation continues until the entire stem is absorbed, leaving the two arms of the Y to enter the bladder separately—one

as the ureter and the other as the vas and ejaculatory duct in the male prostatic urethra (or the vestigial Gartner duct in the female vagina). The two arms of the Y also rotate relative to each other once they contact the UGS/bladder wall, resulting in the ureteric orifice being proximal to the ejaculatory duct orifice. If the ureteric bud reaches the UGS too soon (thought to be due to early budding), over-rotation draws it high and lateral in the bladder wall, leading to inadequate incorporation, insufficient intramural length in the bladder wall, and reflux (Mackie et al, 1975). If the ureteric bud reaches the UGS too late (because of budding late), insufficient rotation occurs, resulting in an ectopic ureter that is drawn distally and medially, often obstructing in the bladder neck region or elsewhere. Furthermore, early or late budding is also thought to mistarget the contact between bud epithelium and the metanephros, leading to renal malformations, dysplasia, hypoplasia, or even agenesis.

FUNCTIONAL ANATOMY OF THE ANTIREFLUX MECHANISM

The phenomenon of VUR represents a balance of several factors. Abnormality in any of these factors alone or in combination will allow or cause the retrograde flow of urine from the bladder up the ureter and ultimately to the renal pelvis and tubules. These factors include the functional integrity of the ureter, the anatomic composition of the UVJ, and the functional dynamics of the bladder.

First, for purposes of reflux prevention, the ureter represents a dynamic conduit, which adequately propels the urine presented to it in a bolus fashion, antegrade, by neuromuscular propagation of peristaltic activity. In so doing, reflux is actively opposed. Moreover, if reflux were to occur, depending on its degree and timing, antegrade flow might be expected to keep refluxing urine from reaching the renal pelvis. The second component is the anatomic design of the UVJ. At the heart of this unique mechanism lies an intramural portion of ureter that travels within the detrusor muscle as it traverses the bladder wall (Fig. 137-1) (Elbadawi, 1972). At the extravascular bladder hiatus, the three muscle layers of the ureter separate. The outer ureteral muscle merges with the outer detrusor muscle to form the Waldeyer sheath, which contributes to formation of the deep trigone. The intramural ureter remains passively compressed by the bladder wall during bladder filling, preventing urine from entering the ureter. Adequate intramural length and fixation of the ureter between its extravascular and intravesical points is required to create this antirefluxing compression valve. Paquin's (1959) early dissections of the UVJ in children revealed an approximately 5:1 ratio of tunnel length to ureteral diameter in nonrefluxing junctions compared with a 1.4:1 ratio in refluxing UVJs (Table 137-2 on the Expert Consult website). Intravesically, the inner muscle of the ureter merges with detrusor muscle to contribute to the superficial trigone. Some of these inner ureteral fibers pass medially to contribute to the intraureteric ridge (Mercier bar). The cellular and molecular details that characterize normal and refluxing UVJs are still unknown. However, it is likely that in addition to architectural deficiencies of tunnel length, abnormalities in uterovesical smooth muscle and extracellular matrix composition and neural function may contribute to reflux (Oswald et al, 2004).

Opening of the UVJ is achieved by active contraction of the longitudinal muscles within the tunnel. This draws the extravascular and intravesical points of the intramural ureter closer together, shortening and widening the tunnel, and allows passage of the urine bolus into the bladder. Indeed, when viewed cystoscopically, a lateral displacement of the ureteric orifice accompanies the classic jet of urine into the bladder. Although such lateral displacement is functionally normal and necessary to permit urine to pass, permanent lateral displacement by virtue of a constitutively short tunnel characterizes the cystoscopic position of the refluxing ureteric orifice. Closure of the UVJ results both from compression of the intramural ureter and a return to its full tunnel length as the ureteral muscle relaxes. Thus active and passive mechanisms dynamically reconfigure the tunnel as needed to allow antegrade passage of

From Paquin AJ. Ureterovesical anastomosis: the description and evaluation of a technique. J Urol 1959;82:573.

Figure 137-1. A, A refluxing ureterovesical junction has the same anatomic features as a non-refluxing orifice, except for inadequate length of the intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. B, Ureterovesical junction in longitudinal section. 1, Photomicrograph; 2, diagrammatic representation. The ureteral muscularis (U) is surrounded by superficial (ss) and deep (ds) periureteral sheaths that extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle (T). The relationship of the superficial sheath to the vesical muscularis (v) is clearly seen. Transverse fascicles in the superior lip of the ureteric orifice belong to the superficial and deep sheaths. No true space separates ureter from bladder. (A, From Glenn J. Urologic surgery. 2nd ed. New York: Harper & Row; 1975; B, from Elbadawi A. Anatomy and function of the urethral sheath. *J Urol* 1972;107:224.)

urine while preventing retrograde flow. Finally, the existence of local efferent and afferent neuromuscular coordination between the UVJ and the periureteral bladder wall is suggested by neurophysiologic studies that induce elevation or decrease in intraluminal UVJ pressure during bladder filling (Shafik, 1996).

KEY POINTS: FUNCTIONAL ANATOMY

- Integrity of the antireflux mechanism depends on balancing the anatomic and functional relationships between the ureter and the bladder.
- Secondary reflux may be of an anatomic or functional origin in the UVJ, bladder, or bladder outlet.

CAUSE OF VESICoureTERAL REFLUX

As mentioned previously, the occurrence of VUR represents a balance of several factors. The degree to which each contributes to the pathologic processes largely defines whether reflux is considered primary or secondary. In general, reflux is considered primary if the main reason for it is a fundamental deficiency in the function of the UVJ antireflux mechanism while the remaining factors (bladder and ureter) remain normal or relatively noncontributory. Secondary reflux, then, implies reflux caused by overwhelming the normal function of the UVJ. Bladder dysfunction of a congenital, acquired, or behavioral nature is often the root cause of secondary reflux. It is also accepted that reflux is often considered secondary if its absence was documented at some point before its detection.

Primary Reflux

As stated earlier, primary reflux represents a congenital defect in the structure and therefore function of the UVJ. Reflux occurs despite

an adequately low-pressure urine storage profile in the bladder. The length-to-diameter ratio of the intramural ureteral tunnel is almost always less than that described by Paquin (1959). Although inadequate tunnel length rather than excessive ureteral diameter usually underlies primary reflux, the dilated ureter often poses a challenge when a nonrefluxing ureterovesicostomy is required. This has traditionally prompted both long tunnels (>5 cm) or reduction of ureteral diameter by tapering, plication, or both to reconstruct a successful antireflux mechanism. On the other hand, construction of a new tunnel with a full 5:1 length-to-diameter ratio may not be absolutely required to correct reflux.

Secondary Reflux

Any number of obstructing bladder pathologic processes can create hostile and excessive storage and emptying pressures that eventually overwhelm a normal antirefluxing intramural flap-valve mechanism. Such abnormalities can be functional or anatomic.

The natural history of reflux to resolve suggests the length-to-diameter ratio of the ureter at the UVJ gradually evolves toward functional competency. However, reflux more likely represents a balance between dynamic storage and voiding characteristics of the bladder and the architectural competency of the UVJ to resist reflux. By this reasoning, it may be suggested that most reflux indeed may be secondary at any given point during the development and chronology of a child's competence with elimination functions.

The most common anatomic obstruction of the bladder in the pediatric population is posterior urethral valves (PUVs). Reflux is present in 48% to 70% of patients with PUV patients (Reuter and Lebowitz, 1985; Puri and Kumar, 1996; Hassan et al, 2003; Priti et al, 2004). Relief of PUV obstruction appears responsible for resolution of reflux in about one third of the patients. In one of these series, 78% of reflux resolved within 6 months of valve ablation (Priti et al, 2004). Such observations argue for the secondary nature of reflux as a result of elevated voiding pressures in PUV bladders.

Even prostatic enlargement and its relief are associated with VUR and its resolution, respectively (Morita, 1987). In females, anatomic bladder obstruction is rare. The most common structural obstruction is from a ureterocele that prolapses into the bladder neck (Merlini and Lelli Chiesa, 2004). In such cases, reflux in a contralateral ureter is likely due to the ensuing outlet obstruction and often resolves with decompression of the ureterocele. In general, then, if relief of the obstruction results in rapid reflux resolution, the reflux was likely secondary.

In contrast to anatomic obstruction, neurofunctional causes of elevated bladder pressures also predispose to VUR. In particular, neurogenic bladder associated with spina bifida is at risk for reflux (Bauer et al, 1982). This fact must be borne in mind during evaluation of the child with UTI. Special attention to the potential for occult spinal dysraphism, including sacral dimple or hairy patch, gluteal cleft abnormality, diminished rectal tone, or significant constipation or encopresis, should prompt consideration of investigation for coexistent spinal cord abnormalities.

Urodynamic extremes that predispose to reflux in the absence of overt neurologic pathologic processes also may exist. Some studies suggest that a secondary aspect to neonatal reflux is a peculiarity of male infants. In a study by Yeung and colleagues (1998), 22 of 24 infants with reflux showing urodynamic evidence of instability (overactivity), inadequate, or obstructive voiding patterns were males. Normal or immature voiding patterns were observed in all infants in the nonrefluxing control group, of which 16 of 21 were male. In infants, higher voiding pressures are associated with reflux, particularly in boys (Chandra et al, 1996), and may contribute to the male preponderance of reflux in infants. Urodynamic evaluation suggests these elevated infant bladder pressures may be due to inadequate sphincter relaxation (Chandra and Maddix, 2000) during this stage of development. However, detrusor activity in such infants is largely normal during filling, with slightly diminished bladder capacities in some (Podesta et al, 2004), though uninhibited activity during filling has been observed, again predominantly in male infants (Yeung et al, 1998). Considering that the high prevalence for reflux in infants coexists with urodynamic evidence of elevated voiding pressures, these observations suggest that infant voiding patterns may be a part of normal development. Thus, even though the UVJ likely matures with age, the interplay between the UVJ and infant voiding patterns may predispose to a form of secondary reflux that resolves with normalization of urodynamic parameters as these infants grow older.

In older children, acquired abnormalities in bladder and bowel function commonly known as *bladder and bowel dysfunction (BBD)* have been associated with reflux. The precise cause of voiding dysfunction is variable but may evolve from a persistence of the expected early attempts to suppress bladder contractions during the toilet training months by volitional contraction of the external sphincter (Allen, 1985). If this behavior becomes prolonged or intensifies, often driven by the child's overwhelming desire for continence, bladder voiding pressures increase. Continence is gradually exchanged for incomplete emptying, resulting in a higher UTI risk. Although investigation of UTI might necessarily diagnose some patients with persistence of primary reflux, the elevated bladder pressures gradually distort bladder and UVJ architecture and may create (secondary) reflux (Koff and Campbell, 1992). Structural failure of the UVJ is likely a critical determinant because high voiding pressures of approximately 100 cm H₂O are common in normal bladders and structurally intact nonrefluxing UVJ. Indeed, with structural failure of the UVJ, reflux occurs easily and at low voiding pressures or during early filling and is a poor prognostic factor for reflux resolution (Koff and Campbell, 1992; Hinman et al, 2002). Uninhibited bladder contraction is the most common urodynamic abnormality associated with reflux in neurologically normal children. In one study of 37 girls with primary reflux, 75% had overactive detrusor contractions (Taylor, 1982). However, the observation that treatment of such patients with oxybutynin can eliminate reflux in up to 80% of refluxing ureters strongly argues that an overactive bladder frequently can be responsible for reflux, by either causing secondary reflux or perpetuating primary reflux

(Koff and Murtagh, 1983; Homsy et al, 1985; Seruca, 1989). Thus it is apparent that primary and secondary reflux may not always be mutually exclusive or that what is perceived as primary reflux in some children may, in fact, be secondary to BBD.

Clinical Correlates

The previous discussion clearly suggests that multiple opportunities exist for modifying the course of reflux if secondary causes are appreciated, identified, and treated. Van Gool and coworkers (1992) identified that 18% of children enrolled in the European arm of the International Reflux Study in Children harbored voiding dysfunction associated with more frequent UTI and greater persistence of reflux compared with those subjects without voiding dysfunction. Similar findings were reported from the recent Swedish Reflux Trial in which a cohort of children 1 year of age to younger than 2 years of age with grade 3 and 4 reflux were assessed and followed for 2 years for lower urinary tract dysfunction prevalence and type (Sillen et al, 2010). Twenty percent of children harbored some form of dysfunction at entry. This dysfunction prevalence increased to 34% at 2 years of follow-up. A negative correlation was found between dysfunction at follow-up and reflux improvement ($P = .002$). In addition, scintigraphic renal abnormalities (defined in Brandström et al, 2010a) at study entry and at follow-up also were associated with dysfunction ($P = .001$). Failure to address voiding abnormalities can adversely affect outcome of antireflux surgery (Koff et al, 1998).

Indeed, meta-analytic evidence recently compiled by the American Urological Association (AUA) Panel on VUR Guidelines now suggests that BBD is by far one of the most critical and modifiable variables that affect VUR management and attendant UTIs. Composite study analysis now indicates that BBD is associated with a higher incidence of UTIs while on antibiotic prophylaxis, as well as after surgical correction of VUR, with less VUR resolution at 24 months from diagnosis and with reduced success of endoscopic surgery. In the studies selected by the panel that qualified as having acceptable levels of evidence, BBD did not appear to reduce the success of open surgical reflux correction (Fig. 137-2).

Thus, although BBD is discussed in detail elsewhere in the text, a thorough evaluation of the toilet-trained child with reflux must recognize dribbling, urgency, or incontinence as signs of coexisting voiding disorders. Girls also will exhibit procrastination about voiding or demonstrate curtsying behavior, and boys may squeeze the penis, in attempts to suppress bladder contractions. The close proximity of the bladder and anal outlets often leads to sympathetic contraction of the anal sphincter as well, resulting in the frequent association of constipation and encopresis with reflux and UTI, in what is probably a mutually aggravating pattern (O'Regan and Yazbeck, 1985; O'Regan et al, 1986; Chase et al, 2004). Constipation must be recognized and eliminated as much as possible to establish optimal conditions for successful spontaneous or surgical resolution of reflux. The initial report of McGuire and colleagues (1981) suggested that pressures in excess of 40 cm H₂O measured at full capacity are associated with reflux and upper tract deterioration. Treatments to maintain pressures below this value result in significant reflux resolution (Flood et al, 1994).

LOWER URINARY TRACT INFECTION AND REFLUX

Reflux is not a general cause of UTI. In the absence of bladder symptoms or inflammation, reflux is most readily considered a clinical accelerant of bacteriuria, by mechanically delivering infected urine to the renal pelvis. Infection-related cystitis is expected to incite bladder irritability and dysuria, upsetting the voiding pattern and lowering the threshold for reflux in a given UVJ. However, animal studies differ on whether infection can perpetuate ureterovesical reflux. In primate studies, surgically created reflux followed by introduction of pathogenic bacteria into the bladder was associated with reflux persistence (Roberts et al, 1988),

Figure 137-2. Dysfunctional elimination syndrome (DES) and urinary tract infection (UTI). CAP, continuous antibiotic prophylaxis. (From Peters CA, Skoog SJ, Arant BS, et al. Summary of the AUA guideline on management of primary vesicoureteral reflux in children. J Urol 2010;184: 1134–44.)

compared with spontaneously occurring primary reflux in the presence of chronic infection (Lewis and Roberts, 1986) in which infection did not delay reflux resolution.

Significant hydroureter and hydronephrosis associated with high-grade reflux could, in theory, act as a reservoir for the repeat antegrade reintroduction of pathogenic organisms to the bladder. Colonized urine might then cyclically reflux retrograde to the upper tracts. Similarly, ureteral atony secondary to the effects of endotoxin could fail to expel infected urine from the upper tracts, but this does not appear to reduce the ultimate resolution of reflux (Roberts and Riopelle, 1978). Indeed, the dilated upper tracts seen in high-grade reflux explored in the randomized prospective controlled Swedish Reflux Trial were associated with a higher rate of recurrent febrile UTI in patients on surveillance without antibiotic prophylaxis (57%) (Brandström et al, 2010b). Reflux correction or antibiotic prophylaxis reduced the recurrent infection rate to approximately 20% ($P = .0001$). Interestingly, the finding was restricted to girls, which may reflect an anatomic predisposition to bacterial colonization of the bladder in girls versus boys; the febrile nature of the infection was likely due to reflux washing of bacteria to the upper tracts and renal parenchyma.

KEY POINTS: LOWER URINARY TRACT INFECTION AND REFLUX

- Reflux is not a general cause of UTI.
- Reflux facilitates pyelonephritis.

GRADING OF REFLUX

Grading systems generally exist to help prognosticate the behavior of the disease they classify. In 1981 the International Reflux Study Committee proposed a system of five grades of reflux that remains in current use today in North America (Duckett and Bellinger, 1982; Lebowitz et al, 1985). Five grades of reflux are currently used to depict the appearance of the ureter, renal pelvis, and calyces as seen on the radiographic contrast images generated by the voiding cystourethrogram (VCUG) (Table 137-3; Fig. 137-3). Using such a system serves several purposes. Grading standardizes the description of the degree of reflux for clinical management of

TABLE 137-3 International Classification of Vesicoureteral Reflux

GRADE	DESCRIPTION
1	Into a nondilated ureter
2	Into the pelvis and calyces without dilation
3	Mild-to-moderate dilation of the ureter, renal pelvis, and calyces with minimal blunting of the fornices
4	Moderate ureteral tortuosity and dilation of the pelvis and calyces
5	Gross dilation of the ureter, pelvis, and calyces; loss of papillary impressions; and ureteral tortuosity

Figure 137-3. International classification of vesicoureteral reflux.

the individual patient and is used for grouping research subjects in the design of clinical studies and trials. Grading facilitates documenting the natural history of the reflux process in the individual patient. It also permits establishing quantitative associations between reflux and other clinical parameters, to determine whether such associations hold clinical relevance. Most importantly, description of initial grade in primary reflux is the most significant parameter associated with prediction of reflux resolution (see later).

Figure 137-4. A refluxing ureter with significant dilation of the lower segment but no distortion of the collecting system may be different from the typical system with grade 2 reflux.

Despite the widespread use of the five-point grading system, several shortcomings exist. For example, the expected concordance between ureteral and calyceal dilation does not always occur (Fig. 137-4). Either the ureter or the calyces may demonstrate dilation out of proportion to the calyces or ureter, respectively. Whether this reflects an anomaly in the biomechanical tissue properties or peristaltic activity of the excessively dilated structure, as compared with the typical refluxing upper tract is unknown. Nevertheless, such anatomy is difficult to grade using the current system. Similarly, it is unknown whether the propensity to either scarring in the face of infection or reflux resolution is altered in such systems.

Attempts also have been made to grade reflux using radionuclide cystography (RNC). Because RNC does not provide discrete images of the ureteral and calyceal architecture required to assign reflux grade, classifying reflux by RNC is difficult. Alternative RNC grading has been proposed (Zhang et al, 1987). This provides reasonable concordance to the objectives of the classic grading system by collapsing grades 2 and 3, as well as grades 4 and 5, into low-grade and high-grade reflux, respectively (Fig. 137-5). The impact of the reduction in grading detail from 5 grades (1 to 5) to 2 (low and high) on understanding reflux pathophysiology and on the design of clinical studies has yet to be determined.

For further details, please see the Expert Consult website.

DIAGNOSIS AND EVALUATION OF VESICoureTERAL REFLUX

Confirmation of Urinary Tract Infection

Because preventable reflux nephropathy is predicated on the combined effects of UTI and reflux, confirming and documenting true UTI is paramount in the appropriate management of the patient with reflux. Many variables are responsible for the accurate assessment and interpretation of UTI in the context of reflux. These include clinical history and presence of fever; age of the patient; circumcision status; method of urine specimen collection, storage,

Figure 137-5. Nuclear voiding cystography showing right-sided reflux. Radionuclide tracer can be quantitated (from left to right) as grade 1 (grade I of the international grading system), grade 2 (grades II to III of the international grading system), and grade 3 (grades IV to V of the international grading system).

and delivery; and the results of urine dipstick and microscopic analyses. Although confirming true pyuria by dipstick or microscopic analysis, in addition to the presence of bacteriuria, will help to differentiate infection from colonization, colonization alone in the presence of reflux still may pose a threat to the upper tracts. Attention to these details cannot be overemphasized because major management decisions, including operative intervention for correction of reflux, often rest solely on a diagnosis of UTI. Conversely, confirming microbial growth in a urine specimen is of little value if the mode of collection is highly suspect and likely to harbor contamination. Confirmation of UTI begins with collection of the urine specimen. If storage is necessary, specimens should be maintained at 4° C until transfer to the laboratory.

For further details, please see the Expert Consult website.

Evaluating Urinary Tract Infection

Numerous factors support a search for reflux in the patient with UTI. The probability of finding VUR in children with a UTI is 29% to 50% (Anonymous, 1981). Furthermore, in some patients, higher grades of reflux may be associated with various degrees of existing renal parenchymal maldevelopment (see earlier section on embryology) (Nakai et al, 2003). In addition, because reflux tends to resolve over time, it is reasonable that UTI is more commonly associated with reflux in younger patients (Smellie et al, 1981b), whose renal parenchyma is at more risk for scarring after pyelonephritis than that of an older child. Smellie and colleagues also suggest that the presence of reflux does not usually provide any unique clinical features in the patient with a UTI. Thus, as with the search for sibling reflux, radiologic investigation of the patient with UTI is tailored to patients who are placed at greatest renal functional risk from the presence of VUR. For this reason, radiographic investigation for VUR until recently has generally been directed to children younger than 5 years of age, all children with a febrile UTI, and any male child with a UTI regardless of age or fever, unless sexually active. More recent guidelines specifically for children under 2 years of age from the American Academy of Pediatrics (AAP) tighten the recommendation for voiding cystography to follow a second rather than the initial febrile UTI, with infection based on stricter culture criteria (see later discussion).

The high repeat UTI rate after a first UTI has prompted a recommendation for some form of VUR workup (Fig. 137-6). However, the current state of the VUR debate makes it difficult to know which patients, by such evaluations, might harbor clinically significant reflux, given how common UTI is in children. Some reassurance can be provided when a voiding study is negative for VUR. However, the parental concern over the invasiveness of the cystogram may first limit the evaluation to ultrasonography only, to rule out any existing gross structural defects. Thus taking the appropriate voiding, fever, and family histories into account, a sonographic study of the bladder and kidneys can be considered a reasonable minimum evaluation in the infant or child after a UTI, concordant with the present AAP guidelines. Even the detection of reflux after treatment for UTI could be of questionable significance if the child is older and/or no fever accompanies the UTI. On the other hand, the presence of structural renal anomalies or significant asymmetry would

Although grading is purely a classification of the appearance of contrast in the upper tract, ascribing an absolute value to the grade has the potential to cast the reflux in unequivocal terms, to the exclusion of other factors that modulate reflux at the time the images are acquired. Inherent bladder dynamics, the bladder outlet, and even ipsilateral UVJ obstruction all influence the degree of reflux at any given assessment (Lebowitz, 1992). Grade, reflux detection, and reflux resolution are all interrelated and are influenced by the degree of bladder filling, the voiding cycle, the number of filling cycles during the contrast cystogram, and whether the reflux occurs during filling or only during voiding. None of these parameters is built into the grading system for reflux used currently. However, given the principal role of a reflux grading system is to help prognosticate reflux resolution, future incorporation of other parameters may provide additional clinical acumen. Finally, it must be remembered that reflux grade is still presently determined by an imaging study that requires invasion of a sensitive anatomic region. For a given reflux grading result, the variables of bladder dynamics, filling, and voiding cannot necessarily be replicated with certainty in a given patient each time he or she is studied. It is reasonable to speculate that reflux grade could easily vary up or down by at least one grade if sequential studies were performed in a given patient. Thus the entire reflux literature, which historically reports results in terms of five separate grades, must be considered with some circumspection because the veracity of grade at the time of the contrast study may be, to some extent, arbitrary.

In infants, specimen collection often will entail the placement of an adhesive urine collection bag over the genitalia. Although topical cleansing of the area is reasonable to reduce contamination and false-positive cultures, care must be taken to avoid introducing the disinfection agent into the specimen. Unfortunately, routine practice is so variable that such guidelines are often difficult to follow or confirm and **microbial contamination of bagged specimens is common. Conversely, this method is most useful if the resulting urine culture is negative.** Although fevers are common in infants, UTI comprises only 5% of children presenting with fever (Hoberman and Wald, 1997). Thus the ability to easily rule out a UTI in the febrile infant with reflux facilitates management. If there is a high clinical suspicion for UTI in an infant, the more accurate method is to obtain a catheterized specimen. Even this method may prove suspect in the uncircumcised infant whose preputial skin is not yet retractable to easily reveal the urethral meatus. In this and other instances in which the urethral route is difficult or compromised in patients of any age, a suprapubic needle aspiration of bladder urine provides the most accurate method of obtaining a urine sample. In the younger child, however, repeated catheterization for specimen acquisition and radiographic assessment (see later discussion) should be considered carefully. This routine practice is coming under greater scrutiny as the long-term sequelae of this invasive maneuver become appreciated (Stashenko and Goldberger, 1998) and could become a factor in patient compliance with follow-up (and therefore management decisions for reflux).

In patients who can void spontaneously, a clean voided mid-stream catch specimen is preferred. The initial urine is discarded because it is rich in periurethral organisms.

The previously mentioned guidelines pertain to patients with both unknown and known reflux status. In the former, the decision to look for reflux will depend on the propensity for acquired reflux nephropathy in the individual patient. In the patient known to have reflux, the prevailing propensity for acquired reflux nephropathy and compliance with proper voiding habits, antibiotic prophylaxis, and timely reporting will influence further management (see later discussion).

Figure 137-6. Urinary tract infection (UTI) history. (From Peters CA, Skoog SJ, Arant BS, et al. Summary of the AUA guideline on management of primary vesicoureteral reflux in children. *J Urol* 2010;184:1134–44.)

support proceeding with a cystogram. More recent studies of racial predilection for reflux have supported a lower prevalence in children of African origin (Askari and Belman, 1982; Horowitz et al, 1999), but the prevalence in children of Hispanic origin (Pinto, 2004) is similar to that of Caucasians.

The advent of prenatal ultrasonography has likely augmented the detection of asymptomatic reflux in newborns, as a result of mass surveillance for persistent postnatal hydronephrosis and the ensuing performance of cystography in these infants. It must be remembered that the sonographic finding of hydronephrosis is generally much more common than hydronephrosis because of a renal moiety actively refluxing at the time of the sonogram. Indeed, there is little correlation between the degree of antenatal hydronephrosis and the existence of reflux (Farhat et al, 2000). A corollary study also demonstrated normal postnatal sonograms in 25% of patients with VUR and antenatal hydronephrosis (Lebowitz, 1993).

ASSESSMENT OF THE LOWER URINARY TRACT

Cystographic Imaging

The basis of reflux detection lies in demonstrating the retrograde passage of an imaging contrast material from the bladder to the ureter and renal pelvicalyceal system. The currently available methodologies require a source of contrast agent in the bladder. Two approaches, the indirect and direct cystograms, can be performed depending on whether the contrast enters the bladder indirectly after excretory urography or directly, usually by urethral catheterization. Indirect cystography, although avoiding the invasive nature of urethral catheterization, is prone to false-positive interpretation as a result of contrast that does not originate from the bladder, remaining in the ureter or pelvis after filtration and antegrade passage, and false-negative results in lower grades of reflux (Conway et al, 1975). However, it has been suggested that the value of indirect cystography may lie in ruling out the presence of VUR (Carlsen et al, 1986).

The VCUG and radionuclide cystogram are the two common forms of direct cystography and constitute the present-day gold standard approaches to reflux detection. More recently, to eliminate the need for ionizing radiation, some studies have demonstrated a growing interest in sonographic detection of reflux using either color Doppler imaging (Haberlik, 1997; Oak et al, 1999; Galia et al, 2004) or echo-enhancing contrast agents (Berrocal et al, 2001; Darge et al, 2001; Darge and Troeger, 2002; McEwing et al, 2002; Tasic and Todorovska, 2003; Valentini et al, 2004; Vassiou et al,

2004; Darge et al, 2005). Direct imaging of reflux is affected by several parameters. These include bladder contraction during voiding, the fluid volume instilled into the bladder, and presence of infection and therefore inflammation of the UVJ mucosa. Reflux may occur during filling or only during the active bladder contraction associated with voiding. Consequently, if a patient is unable to void in the artificial setting of the radiography suite, false-negative results may ensue. More importantly, even during voiding, reflux may not be demonstrated on a single filling-voiding cycle. Several studies have demonstrated a roughly 12% to 20% greater detection rate for VUR if a cyclic study is performed (Paltiel et al, 1992; Papadopolou et al, 2002; Novljan et al, 2003). A cyclic VCUG involves a second or third cycle of bladder filling and emptying under fluoroscopic observation. A similar cyclic strategy is commonly employed for the RNC as well (Fettich and Kenda, 1992). Reflux also may be demonstrated during catheter filling of the bladder. Because filling assumes far lower intravesical pressure than that of voiding, reflux during filling, or passive reflux, is generally considered a poor prognostic sign for reflux resolution and suggests the presence of a fixed decompensation of the UVJ. This is a common finding in patients with acquired or neurogenic voiding dysfunction, wherein high-resistance voiding gradually remodels the bladder wall and UVJ, leading to complete failure of the latter's antireflux mechanism and immediate reflux at virtually any volume of the filling phase (Koff, 1992). This is in contrast to reflux that occurs only during the higher pressure milieu of bladder emptying and contraction. Thus technical inconsistencies in the ratio of instilled volume-to-bladder capacity during the radiographic technique can lead to variations in rates of reflux detection: if the bladder is overfilled or underfilled for a given degree of progressive UVJ incompetency, reflux may be overdetected or underdetected, respectively.

One difficult dilemma in the performance of voiding studies involves cystography during active infection. On one hand, some UVJs maintain only borderline antireflux mechanisms, which are competent in a sterile milieu but become incompetent from edema and inflammation associated with mucosal inflammation during cystitis. Such patients may have VCUG studies negative for reflux in the absence of infection but suffer from repeated pyelonephritic episodes. Cystograms in such patients may demonstrate reflux if obtained during clinically active infection, whereas cystogram obtained in the presence of positive urine cultures alone may not (Gross and Lebowitz, 1981). On the other hand, evoking reflux during an active cystitis, by definition, will transmit bacteria to the upper urinary tract and renal pelvis and risks iatrogenic pyelonephritis. Nevertheless, the general consensus has been to delay the voiding study for at least a week or longer to allow for adequate recovery from the acute infection episode (Craig et al, 1997). Only if it is imperative to make the diagnosis of reflux in children with a history of recurrent pyelonephritis and repeatedly negative voiding studies in the intercurrent periods should cystography during UTI be considered.

The VCUG is a fluoroscopic study that provides information on both the functional dynamics and structural anatomy of the urinary tract. The detailed technique of the VCUG is discussed more fully elsewhere in the text. Bladder contrast is instilled by gravity after urethral catheterization. Bladder capacity is recorded when contrast influx ceases. Static images record bladder contour, presence of diverticula or ureteroceles, grade of reflux, configuration and blunting of calyces, and intrarenal reflux. Passive or active reflux is demonstrated dynamically during fluoroscopy while filling and voiding, respectively. In addition, bladder neck anatomy, funneling or dilation, and urethral patency are parameters derived from the VCUG. Delayed or postvoid films are crucial in documenting clearance of contrast from the upper tracts because retained contrast, particularly with dilated pelvicalyceal systems, could signify the presence of a concomitant UPJ obstruction (UPJO), either primarily or secondarily as a result of distortion of the UPJ by massive retrograde filling of the pelvis by the reflux (Hollowell et al, 1989). If both the UPJ and UVJ meet criteria for operative repair, the UPJ should be repaired first to avoid the incipient obstruction that may ensue if resistance is added to the UVJ when reflux is

Figure 137-7. Radionuclide cystogram showing right-sided reflux that worsens with bladder filling. The upper collecting system drains fully with voiding.

corrected (Hollowell et al, 1989). With care, both processes may be repaired simultaneously when it is clear that they are independent significant problems.

The RNC has historically enjoyed a reputation for requiring approximately 1% the radiation exposure generated by the VCUG (Blaufox et al, 1971; Diamond et al, 1996a). Presently, the reduced radiation requirements of modern digital techniques have significantly narrowed the difference between fluoroscopy and RNC. Although little anatomic detail is afforded by the RNC, it is ideal as both a screening modality and for monitoring the natural history or surgical follow-up of reflux. In contrast to the VCUG, the instilled bladder contrast material, usually technetium-99m pertechnetate, is the radiation source. Reflux is detected on scintigraphic gamma camera images (Fig. 137-7). Lack of confounding imaging densities typical of fluoroscopy, as well as the ability to obtain prolonged exposures, allow for greater sensitivity of the RNC in grade 2 to 5 reflux. Ironically, grade 1 reflux into the distal ureter is often poorly detected because of the overlying exposure generated by contrast within the bladder. Thus RNC and VCUG imaging can be used complementarily, balancing radiation exposure with the need for dynamic information and anatomic detail. Notwithstanding the previous discussion, modern digital fluoroscopic equipment has further reduced the radiation exposure of conventional fluoroscopy, thereby narrowing the difference in radiation exposure between the two modalities.

Another modality gaining popularity in some centers is ultrasonic cystography to detect reflux. Modern transducers coupled with the use of echo-enhancing contrast agents can image reflux well in older children (Novljan et al, 2003; Riccabona et al, 2003; Tasic and Todorovska, 2003; Galia et al, 2004), but the technique remains of limited use in neonates (McEwing et al, 2002). Furthermore, although radiation exposure is eliminated, bladder catheterization remains a necessary feature with this approach.

Diagnostic Controversies: Challenging the Assessment of Reflux

The well-recognized distress of the family and patient associated with urethral catheterization, particularly in children, coupled with the advent of low-morbidity outpatient correction of reflux using endoscopic approaches appears to be challenging conventional reflux management and therapy. All aspects of VUR, including modern incidence of renal scarring and failure, peak ages of renal susceptibility, and indications for reflux correction, including the assumption that permanent correction of reflux is an absolute necessity, are coming under scrutiny. This has given rise to added pressure to avoid bladder catheterization. The cystogram can have

traumatic after effects in young patients (Stashinko and Goldberger, 1998; Elder, 2005) and must be approached with sensitivity and awareness of the developmental stage of the patient. Sedation (Stokland et al, 2003), topical urethral anesthetic (Gerard et al, 2003), and more recently hypnosis (Butler et al, 2005) have all been effective in mitigating the deleterious psychological effects of cystography. Nevertheless, it is clear that parental perception of the nature of the medical modalities involved in reflux management will influence their choice of therapy for their children (Ogan et al, 2001). This should in no way be construed as license for the abandonment of conventional observational therapy, including antibiotic prophylaxis and periodic cystography in favor of immediate reflux correction in all patients (Aaronson, 2005). Rather, the evolution of less invasive imaging modalities for reflux detection and reduced morbidity of reflux correction should be encouraged in parallel.

Uroflowmetry

Evaluation of the lower urinary tract during clinical assessment of VUR cannot rely solely on imaging. Because reflux is a dynamic phenomenon, the prevailing functional status of the bladder also must be considered. Although full pressure-volume urodynamic studies of the bladder are not required in all patients with reflux, a minimal survey of bladder emptying characteristics can be obtained by uroflowmetry. The details of uroflowmetry technique are discussed elsewhere in the text. In patients with reflux, it is important to establish whether the bladder outlet is functioning relatively normally or harbors more resistive characteristics that are highly prevalent in younger patients. Elements of the uroflow such as lack of smoothness of the flow-velocity curve suggest incomplete relaxation of the bladder outlet during voiding. This implies the existence or development of relatively higher pressures during voiding, which could delay the natural history of reflux resolution or even perpetuate reflux. An increased postvoid residual volume may be a risk factor for UTI. In the setting of passive reflux, carrying infected postvoid residual urine also can lead to ascending infection and pyelonephritis.

Top-Down Approach

The top-down approach is an interesting concept based on the notion that only clinically relevant reflux with potential to cause renal injury is worthy of uncovering, with the critical assumption that VUR in the absence of scintigraphic renal abnormality is unlikely to cause future renal damage. Only a dimercaptosuccinic acid (DMSA) renal scan is obtained after a febrile UTI, with cystography reserved only for patients with abnormal scintigraphy findings. Children with a negative DMSA scan undergo no further evaluation unless they develop recurrent UTI, in which case a VCUG should be obtained.

Hansson and colleagues (2004) retrospectively reviewed 303 children younger than 2 years of age who had undergone evaluation by DMSA and VCUG within 3 months of their first UTI. Although 82% of these infections were febrile, VUR was found in only 26% of the children (80 in 303), 66% of whom had abnormal DMSA scans, and no abnormalities were detected in the remaining 27 patients. An approach based on identifying renal cortical abnormalities before obtaining a VCUG would have identified the 66% of children with VUR presumably at risk for further scarring, and it would have excluded 120 children (40%) without VUR or renal abnormalities from an unnecessary VCUG.

Implementation of a top-down approach would obviously not have detected 34% (27 in 80) of the cases of VUR. However, the patients in Hansson's study did receive prophylaxis, because the top-down approach was being studied only from a theoretic viewpoint. In applying the top-down approach, these infants would not have been started on antibiotic prophylaxis and potentially might have been at risk to develop recurrent UTI. However, in 74% (27 in 80) of these patients, VUR was low grade and the remaining 7 cases (grade 3 to 5 VUR) either resolved or improved significantly during

TABLE 137-4 American Academy of Pediatrics Clinical Practice Guideline on Febrile Urinary Tract Infection in Febrile Infants and Young Children: Key Updates

AREA OF MANAGEMENT	UPDATES FROM THE 1999 GUIDELINE
Diagnosis	Both an abnormal urinalysis result and a positive urine culture result are needed to confirm inflammation A positive culture result is defined as at least 50,000 colony-forming units per milliliter, rather than the previous criterion of at least 100,000 colony-forming units per milliliter Guidance is added for using clinical criteria to establish a threshold to decide whether to obtain a urine specimen
Treatment	Oral treatment is as effective as parenteral treatment
Imaging	Voiding cystourethrography is not recommended routinely after the first febrile urinary tract infection; ultrasonography should include the bladder and kidneys
Follow-up	Emphasis is on urine testing with subsequent febrile illnesses, rather than on regularly repeated urine cultures after treatment

NOTE: The guideline applies to infants and children 2 to 24 months of age with unexplained fever.

Data from Roberts KB; Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management. Urinary tract infection: clinical practice guideline for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. *Pediatrics* 2011;128:595–610.

a 2-year follow-up period, with one of them developing a renal scar on repeat DMSA scintigraphy.

In a follow-up study from the same institution, [Preda and colleagues \(2007\)](#) prospectively confirmed these observations in 290 children younger than 1 year of age with UTI (79% febrile) with VCUG and DMSA renal scans. Of the patients, 51% had positive scans, including 85% (44 in 52) of the children later found to have VUR. Of the 8 cases of VUR with normal DMSA scans, 7 were low grade, with the remaining boy having grade 3 VUR with no acquired renal scars in follow-up despite an episode of breakthrough UTI.

The potential ability to detect children with significant VUR who are at risk for renal scarring while avoiding invasive evaluation and unnecessary treatment of those who are not is clearly appealing. However, a recent meta-analysis has shown the top-down approach to perform poorly at detecting high-grade VUR with a sensitivity and specificity of only 79% and 53%, respectively ([Mantadakis et al, 2011](#)). These data underscore the importance of further prospective analysis with longer follow-up to establish the validity and safety of the top-down approach.

National Institutes for Clinical Excellence Guidelines

In an attempt to streamline the investigations and treatment in infants and children presenting with UTI, the National Institutes for Clinical Excellence (NICE) in the United Kingdom proposed a set of guidelines aimed at reducing morbidity, antibiotic usage, and cost ([Baumer and Jones, 2007](#)). Investigations are limited to a sonogram of the urinary tract, with cystography reserved for infants younger than 6 months and in older infants when dilation is observed by ultrasonography. They do not recommend early DMSA renal scans to confirm or exclude renal involvement and rely solely on ultrasonography in sicker patients to determine the need for further investigation. The major criticism to this approach lies in the poor correlation between the appearance of the kidneys on ultrasonography and the presence of renal parenchymal changes or the presence and grade of VUR. The NICE committee did not provide any clinical outcomes to validate these guidelines, and until confirmation of the safety of this approach is established prospectively, it cannot be recommended for general clinical use.

American Academy of Pediatrics Guidelines for Febrile Urinary Tract Infection Diagnosis and Management in Young Children

In 2011 the AAP released revised guidelines for the diagnosis and management of UTI in children 2 to 24 months of age ([Roberts](#)

[et al, 2011](#)). The guidelines were based on a rigorous review of the literature and six new randomized controlled trials of antibiotic prophylaxis to prevent recurrent UTI. The guidelines are summarized in [Table 137-4](#).

To establish the diagnosis, stricter infection criteria were suggested, including a lowered threshold for urine culture colony-forming units per milliliter (50,000 from 100,000) as well as the additional requirement of an abnormal urinalysis result. Oral and parenteral antibiotic treatments are now considered equally efficacious. The use of renal-bladder sonography retains its traditional and important role in structural assessment. However, the most important deviation from past practice is the AAP recommendation to forgo a VCUG after the *first* febrile UTI. Emphasis is now placed on this familiar cystographic imaging study and on follow-up after a *second* or subsequent febrile UTI. This essentially shifts the potential burden of postinfection injury after a single isolated febrile UTI, which may never recur, to one or more subsequent febrile UTI episodes. This position also does not account for preexisting VUR-related developmental renal abnormalities that were not sustained by UTI per se.

However, the recommendation to forgo VCUG after initial febrile UTI is qualified. If hydronephrosis, sonographic indications of possible renal scarring or dysmorphism, or other findings that suggest high-grade VUR or obstructive uropathy are present, the VCUG should be obtained. Similarly, any complex or clinically atypical scenario supports obtaining the VCUG after a first febrile UTI. It should be remembered that a positive finding of VUR by VCUG does not occur in many patients after a first febrile UTI. Thus this newer recommendation would seem to balance the incidence of first febrile UTI in infants with the attendant invasiveness, radiation exposure, and patient and family trepidation surrounding a VCUG. Notwithstanding these developments, at least one study has suggested that even with vetting of the decision to proceed with a VCUG using sonographic evidence of renal abnormality after initial febrile UTI, a clinically significant VUR diagnosis still may be delayed or missed because scintigraphic renal abnormalities may exist even in the presence of a normal renal ultrasonography. The crux of this concern lies in details of the degree and significance of such nuclear imaging abnormalities, which were not discussed in the study ([Suson and Mathews, 2014](#)).

Cystoscopy and the Positioning of the Instillation of Contrast Cystogram

Modern management of reflux does not include routine cystoscopy. It is rare for cystoscopy to add any information that will alter

management of a patient with reflux, either at the time of initial diagnosis or during follow-up. Its routine use, especially in children with UTI or reflux, should be considered an anachronism. Similarly, the appearance and configuration of the ureteric orifices and intramural tunnel length that are afforded by cystoscopy and once considered useful parameters have over time provided little correlation with either the diagnosis or grade of reflux (Duckett, 1983). Cystoscopy can provide useful information immediately before open surgery, such as confirmation of orifice position and duplication and the proximity of diverticula to the orifice, and clarify urethral patency if indicated. Similarly, such cystoscopic parameters will become immediately available in all patients at the time of endoscopic reflux correction.

A recently developed, although still controversial (Elder, 2005), cystoscopic modality termed *positioning of the instillation of contrast at the ureteric orifice (the PIC technique)* purports to detect reflux under general anesthesia in patients with a history of febrile UTIs but a normal VCUG. The technique of PIC cystography (Edmondson et al, 2006) involves cystoscopy using a 9.5- or 14-Fr rigid cystoscope. With the bladder empty, the cystoscope beak is positioned close to and facing the ureteric orifice. Contrast is instilled at the ureteric orifice using the irrigation port of the cystoscope from a height of 1 meter above the bladder. Fluoroscopic spot imaging is done simultaneously with the instillation. PIC-VUR is confirmed if retrograde flow of contrast into the ureter/kidney pelvis is observed. The bladder is emptied before the procedure is repeated on the contralateral side.

It is conceivable that antireflux mechanisms may be barely functional in some patients with recurrent UTI. The unique but unphysiologic nature of the PIC technique may then reveal reflux in such cases. Furthermore, PIC cystography does not allow for age-adjusted instillation pressures; some pressures may be too high in younger patients and may be creating iatrogenic reflux rather than unmasking relevant, physiologically borderline reflux.

A multi-institutional study by the PIC Cystography Group (Hagerty et al, 2008) examined the clinical significance of reflux discovered by PIC in 118 children with a history of febrile UTIs and negative VCUGs. VUR diagnosed by PIC was treated by surgery (endoscopic injection in 104 patients, reimplantation in 3) or by antimicrobial prophylaxis (11 patients). In the 98 evaluable patients, VUR grade was 1 to 3 and was unilateral in 34 patients and bilateral in 64 patients. Treating occult VUR identified by PIC cystography, with either antibiotics or surgery, reduced the incidence rate of febrile UTI by 20-fold (from 0.161 per patient per month before PIC-VUR treatment to 0.008 per patient per month after treatment).

It is generally believed that VUR does not cause UTI; however, in this nonrandomized study (with the patients acting as their own controls), PIC cystography provides some evidence and rationale for antireflux therapy in a new subset of patients, particularly because endoscopic correction could theoretically and easily follow the fluoroscopy at the same time. However, **the urologist must exercise caution in this approach until prospective studies randomizing patients with PIC-VUR to treatment or observation confirm its clinical importance.**

ASSESSMENT OF THE UPPER URINARY TRACT

Rationale for Serial Assessment of Upper Tracts

The known effects of VUR on the upper tracts are largely what direct the need for reflux diagnosis and correction. Pyelonephritis propagated by reflux causes renal scarring, impedes attainment of full renal growth potential, and increases risk for renovascular hypertension. Therefore imaging of the upper tracts is directed at assessing renal structure and function, with attention to the aforementioned parameters. A fundamental goal in upper tract imaging with VUR is to ascertain whether abnormalities are due to ongoing or resolved reflux and differentiate them from intrinsic developmental disturbances, medical renal disease, or antegrade flow resistance. Almost always, particularly in the youngest patients in whom VUR has the

greatest potential to adversely affect renal function, these goals are best achieved through serial imaging of the kidneys over a period of months to years.

However, a meta-analysis of 63 studies assessing the value of routine diagnostic imaging after initial UTI in children for the prevention of renal damage found no accurate evidence to support this practice (Dick and Feldman, 1996). Many observational studies raised concern for the sequelae of UTIs and highlighted the potential for successful intervention. The reason to image the upper tracts after a UTI may occur with or without knowledge of the reflux status of the lower tract. Reflux status may be known, suspected, or completely unknown. These three considerations, coupled with the age of the patient, gender, race, family history of reflux, and bladder functional status serve as a guide to selective imaging, which attempts to balance intensity of imaging studies with propensity for renal damage.

Renal Sonography

The mainstay of renal imaging in VUR management is ultrasonography. As a nonionizing, noninvasive imaging platform, coupled with its ability to assess renal vasculature, it is ideally suited to serial follow-up of renal growth and development. Ultrasonography has supplanted routine excretory urography as the imaging modality of choice to monitor renal status over time.

Ultrasonography lends itself well to quantitative assessment of renal dimensions (Rodriguez et al, 2001; Chen et al, 2002), which then can be used to follow renal growth over time. Renal growth can be referenced to standard renal growth curves. In reflux diagnosed in the neonatal period, baseline renal dimensions are obtained and appropriate renal growth can be monitored over time. The impact of any intercurrent febrile urinary infection can be gauged by observing the effects on renal growth. Similarly, if the UTI history between follow-up visits for reflux is unclear, serial assessment of renal dimensions can help the urologist advise on the need for further assessment of renal function by scintigraphy or on the need for reflux correction. Indeed, in the presence of reflux, modern postnatal renal sonography provides excellent correlation between renal length and scintigraphic hypoplasia (Farhat et al, 2002a).

Ultrasonography also images the degree of corticomedullary differentiation in the kidney. Loss of corticomedullary differentiation, or an increase in the overall echogenicity of the kidney, is associated with some degree of renal functional impairment. In neonates in particular, these parameters can be useful in assessing overall status of a renal unit in the context of higher grades of reflux, even before any history of UTI or pyelonephritis has occurred. Coupled with a relatively smaller ipsilateral kidney, loss of corticomedullary differentiation or increased echogenicity suggests a degree of intrinsic renal dysplasia that developmentally accompanies high-grade reflux. In the neonate with no infection history, such findings should not be confused with renal scarring, which is the direct sequela of inflammation and infectious pyelonephritis. In general, the routine sonogram is noninvasive, is performed relatively quickly, and does not require intravenous access for contrast agents.

Notwithstanding the value of renal sonography, it must be remembered that a single ultrasound study cannot reliably diagnose VUR. Although it is tempting to speculate on the presence of reflux in the presence of postnatal hydronephrosis on sonography, particularly of higher grades, there is no significant correlation between a normal sonogram and the absence of reflux (Farhat et al, 2000; Zamir et al, 2004). Similarly, renal sonography is limited in its ability to visualize renal cortical abnormalities. Sonography is better suited to the noninvasive detection of larger cortical defects or renal size asymmetry (Merguerian et al, 1999).

Modern enhancements in ultrasound technology permit imaging of perfusion abnormalities in tissue. In reflux nephropathy using color Doppler ultrasonography, renal resistive index measurements derived from blood flow in interlobar and arcuate arteries are significantly increased in higher grades of reflux and correlate positively with scintigraphic findings from the same renal unit (Radmayr et al, 1999). Resistive indices are also higher in patients with bona

Figure 137-8. Dimercaptosuccinic acid renal scintigraphy. Pinhole images show a normal left kidney and a right kidney with multiple cortical defects.

fide pyelonephritis confirmed by nuclear scintigraphy compared with patients with lower UTI alone (Ozcelik et al, 2004). Animal studies also have demonstrated that contrast-enhanced harmonic ultrasonography can detect histologically confirmed regions of reflux-induced pyelonephritis with great sensitivity and more than 80% positive and negative predictive values (Farhat et al, 2002b).

Renal Scintigraphy

The gold standard for imaging functioning renal parenchyma is scintigraphy using ^{99m}Tc -labeled DMSA. The radiotracer is taken up only by functioning proximal tubular tissue mass, where it binds for several hours. The uptake of DMSA provides a good proportional representation of glomerular filtration (Taylor et al, 1982). Because pyelonephritis impairs tubular uptake of radiotracer, these areas will fail to radioemit photons and appear as unexposed or underexposed regions in the resultant renal cortical images (Fig. 137-8). Although many such affected areas in the kidney resolve, especially if prompt medical treatment is possible (Fernández-Menéndez et al, 2003), when they persist, irreversible renal damage or scarring is said to have occurred (Rushton and Majd, 1992). In a study of 79 children followed for 1 to 4 years, DMSA scanning provided 98% sensitivity and 92% specificity for scar detection (Merrick et al, 1980). Although Rushton's study suggested that subsequent scarring was independent of the presence or absence of VUR (Rushton and Majd, 1992), a more recent meta-analysis found that reflux conferred an approximately three-fold increased risk for detecting renal cortical abnormalities after infection (Faust et al, 2009). Indeed, considering the overall incidence of pyelonephritis in children, VUR is present in 22% to 39% of such patients (Hoberman et al, 2003; Lin et al, 2003). Nonetheless, the importance of VUR lies in the realization that it remains a spontaneously resolving or surgically treatable cause for this ascending group of renal infections (Majd et al, 1991).

One advance in nuclear scintigraphy of the kidneys is single-photon emission computed tomography (SPECT imaging). This approach reconstructs three-dimensional (3D) images of the renal cortical architecture, which can be viewed in any aspect in 360 degrees of rotation. Although SPECT images provide slightly higher sensitivity for detection of cortical defects, they do not add appreciably to standard pinhole DMSA images in the clinical management of reflux (Majd et al, 1996).

Despite the well-established guidelines for renal cortical scintigraphy from the Society of Nuclear Medicine (Mandell et al, 2003), investigators in the Randomized Intervention in Vesicoureteral Reflux (RIVUR) study reported a significant degree of interinstitutional variability in how DMSA scans are performed with 17% of RIVUR DMSA scans rejected because of poor quality (Ziessman and Majd, 2009).

Much has been written in the literature on the role of DMSA scanning in the management of VUR, as an indirect entrée to the diagnosis of reflux itself, for the detection of reflux-associated renal damage and acute pyelonephritic changes, and for follow-up of

reflux. However, no consensus exists on the precise use of DMSA scanning in reflux management. For example, growing concern over the nature and frequency of voiding studies has prompted some to propose cystography after UTI only in children with persistent postinfection renal lesions on DMSA scan, citing that only a minority of post-UTI cystograms are positive for reflux (Hansson et al, 2004). DMSA and ultrasonography are often used complementarily, particularly when knowledge of relative renal function is desired (Riccabona et al, 1993). As a general rule, the utility of scintigraphy can best be appreciated in the context of the data it provides relevant to reflux: imaging cortical defects and relative renal function. The usefulness of this information will depend on which associated clinical and radiology data are at hand. If reflux and infection history are unclear or unknown in a new patient referred for evaluation after UTI, scintigraphy can provide the gold standard for demonstration of cortical defects for any reason and help with counseling on additional studies. If the significance or febrile nature of a potential pyelonephritis is unclear, particularly in a younger patient, a follow-up DMSA scan 4 to 6 months after UTI can rule out subsequent scarring, particularly if a normal scan exists from a prior evaluation. DMSA scanning can be particularly useful if the diagnosis of pyelonephritis is unclear during an acute infection. Confirmation of photopenic radioemission and acute pyelonephritis can help ensure that adequate antimicrobial therapy is provided. If surgical intervention is planned and significant renal asymmetry exists on ultrasonography, quantification of relative function by scintigraphy can help in the decision between reflux correction and nephrectomy.

DMSA scanning also has demonstrated that congenital cortical maldevelopment can exist, particularly in high-grade reflux, even in the absence of any history of UTI or outlet obstruction (Wallin and Bajc, 1994; Nguyen et al, 2000). This underscores the fact that cortical defects detected by DMSA scanning are not always the by-product of infection; all DMSA defects are not necessarily scars. The distinction is an important one in the design of clinical studies and interpretation of the reflux literature, where congenital cortical defects may be erroneously construed and evaluated as if they were due to postinfection scarring. One corollary to this observation is that scintigraphic renal defects detected for the first time in a child in whom the reflux history from birth cannot be confidently known could be secondary to reflux-associated pyelonephritic scarring, even though the reflux has resolved by the time of the study. Failure to appreciate that reflux often resolves in early childhood before scanning detects cortical defects for the first time makes it difficult to know whether these defects were associated with reflux.

CORTICAL DEFECTS

Congenital Defects versus Acquired Scar

The term *scar* is defined as fibrous tissue replacing normal tissues destroyed by injury or disease. In a renal context, the term is most accurately used to describe the fibrous, contracted regions of the kidney that have been destroyed by infection. This scar tissue often appears as a smaller and photopenic area by scintigraphy or, when larger, as hyperechoic and shrunken areas on sonographic images. The importance of such scars lies in the realization that they are the preventable complication of pyelonephritis, the latter being directly influenced by VUR in the presence of a bladder infection.

However, VUR, particularly of higher grades, may result in renal maldevelopment that often appears scintigraphically or sonographically identical to postinfection pyelonephritic scars (Murer et al, 2007; Peters and Rushton, 2010). Thus, over time in the literature and in clinical practice, the terminology of scarring, which is ideally defined to describe an end product of infection, has become contaminated by the inclusion of reflux-associated congenital dysmorphism. However, until such time that primary reflux can be averted prenatally (Gobet et al, 1998) or during the early postnatal phase of continued renal development, dysmorphism will remain a non-preventable developmental sequela of reflux. Failure to appreciate

this important distinction has tainted and confused study design and interpretation in the reflux literature.

Reflux-Associated Renal Dysmorphism

The association of renal maldevelopment with the highest grades of reflux is expected by the theory of [Mackie and Stephens \(1975\)](#), which suggests that an abnormal origin of the ureteric bud will interact suboptimally with the metanephric blastema ([Fig. 137-9](#) on the Expert Consult website). The latter process is currently believed to be the likely cause of renal dysmorphism associated with reflux. Several studies have confirmed the association between VUR and a smaller than normal ipsilateral kidney, an overall reduced relative renal function, and global ([Najmaldin et al, 1990](#); [Burge et al, 1992](#)) or focal ([Risdon, 1993](#)) areas of poor uptake by scintigraphy. These infants tend to be males, and the preponderance of refluxing renal units are grade 4 or 5 ([Marra et al, 1994, 2004](#)) ([Table 137-5](#); [Fig. 137-10](#)). Indeed, boys tend to be spared an infectious cause of reflux-associated scarring because they have a lower incidence of recurrent UTIs ([Wennerstrom et al, 2000](#)).

Renal dysplasia is not unique to primary isolated VUR but also may occur in a variety of urologic settings. Duplex renal moieties ([Mackie et al, 1975](#)), prune-belly syndrome ([Manivel et al, 1989](#)), and posterior valves may exhibit reflux-associated renal dysmorphism, particularly when the grade of reflux has been high.

Requirement for Urinary Microorganisms

It is now firmly established that nephropathy from primary VUR requires the colonization of urine with pathogenic bacteria in the face of normal voiding dynamics. Indeed, the basis of current expectant medical management of reflux is to maintain urinary sterility while allowing reflux to resolve naturally. In the absence of infection, sterile urinary reflux is insufficient to cause renal damage. This concept has been most definitively demonstrated by the elegant series of experiments by [Ransley and Risdon \(1981\)](#). Reflux was induced experimentally in a pig model by unroofing the intravesical ureteral tunnel. Only if the urine was subsequently infected could pyelonephritis and reflux nephropathy be induced. Without urine infection, no nephropathy could be created ([Ransley and Risdon, 1981](#)). Large clinical studies have reiterated these experimental findings, demonstrating new reflux-associated scarring only in children with recurrent UTIs ([Smellie et al, 1975](#); [Huland and Busch, 1984](#)). These observations conflict somewhat with earlier animal studies by [Hodson and colleagues \(1975\)](#), which induced reflux with sterile urine. However, bladder outflow obstruction also was included in this model, leading to a finding of atrophic pyelonephritis similar to obstructive nephropathy. Scarring was nevertheless intensified by the presence of urinary microorganisms. Thus abnormal hydrodynamic bladder characteristics may modulate even sterile reflux, but reflux is unlikely to be of any clinical significance in the absence of

TABLE 137-5 Congenital Renal Scarring

GRADE OF VESICoureTERAL REFLUX	NO. PATIENTS NORMAL (%)	SLIGHT DAMAGE (%)	SEVERE DAMAGE (%)

Modified from Marra G, Barbieri G, Dell'Agnola CA, et al. Congenital renal damage associated with primary vesicoureteric reflux. *Arch Dis Child Fetal Neonatal* Ed 1994;70:F147.

Figure 137-10. A, Massive reflux in a boy with antenatally diagnosed hydronephrosis. B, Ultrasonography demonstrating a kidney with poor internal differentiation. No function was seen on scan.

Figure 137-9. Classification of ureteric orifice position. Obstruction usually occurs in the caudo zone, and ureters positioned in the cranio zone are likely to result in reflux. Ureters positioned in the normal (N.) zone are associated with normal kidneys. Because of ureteric bud abnormality, renal dysplasia occurs with ureters projecting from both abnormal positions. (From Mackie GC, Stephens FD. Duplex kidneys: a correlation of renal dysplasia with position of the ureteral orifice. *J Urol* 1975;114:274.)

infection with relatively normal bladder function. These earlier observations of Hodson, however, underscore the importance of normalizing bladder and bowel function while awaiting reflux resolution.

KEY POINTS: DIAGNOSIS AND EVALUATION OF VESICoureTERAL REFLUX

- The method of urine collection and the presence of pyuria are of utmost importance in the diagnosis of UTI to avoid false-positive culture results.
- Radiologic studies should be tailored to age, gender, and mode of manifestation (i.e., fever).
- The gold standard study for the diagnosis of reflux requires bladder catheterization.
- Nuclear cystograms, though more sensitive, provide much less anatomic detail than does a VCUG.
- Parental perceptions of reflux management must be considered when treating a child with reflux.
- Routine cystoscopy is **contraindicated** in reflux management.
- Upper tract assessment is based on serial studies.
- The intensity of upper tract studies should be proportional to the propensity for renal damage.
- The challenge in imaging is to differentiate congenital reflux-associated renal dysmorphism from scarring acquired after infection.

Pathophysiology of Acquired Scarring

Renal scarring is a sequela of infectious pyelonephritis. A full discussion of the pathophysiology of renal scarring is covered elsewhere in the text. However, VUR exploits several conditions that predispose to scarring. Most importantly, **reflux provides a mechanical hydrodynamic mechanism that facilitates the ascension of microorganisms from the bladder to the kidneys. Thus reflux may be considered an accelerant for renal tissue infection after bacterial colonization of the bladder.** This principle has been confirmed by studies showing an increased incidence of pyelonephritis in higher grade reflux compared with lower grade reflux (Majd et al, 1991). Furthermore, the frequency of scarring itself appears to be directly proportional to the grade of reflux with which it is associated (Winter et al, 1983; Weiss et al, 1992a). This principle is also supported by observations after reflux correction. In one study of 74 patients in whom preoperative and postoperative scintigraphy studies were available, more than 90% of renal units corrected for reflux showed no new scars during a mean follow-up period of 19 months, despite asymptomatic bacteriuria in 47% of the patients during follow-up (Choi et al, 1999).

Age

The kidney's predilection for postpyelonephritic scarring is inversely proportional to age. This point is a guiding principle that must be considered in all decisions regarding reflux diagnosis and choice of therapy. The greatest risk for postinfectious renal scarring occurs within the first year of life (Winberg, 1992). Similarly, patients younger than 4 years are more prone to developing scarring after a single UTI than older children (Smellie and Normand, 1985), though scarring may still occur beyond 5 years of age (Smellie and Normand, 1985; Benador et al, 1997). Indeed, although younger patients are the most vulnerable to scarring, scarring in older children is often the result of late diagnosis, delayed or inadequate treatment of infection, and social factors that often interfere with patient management. Thus, in older children with reflux in whom relinquishing care from the urologist back to the family physician is being considered, it is vital that fundamental principles of an adequate clinical index of suspicion for UTI and

prompt UTI management be reiterated before transfer (Coulthard, 2002; Coulthard et al, 2009).

The seminal studies of Ransley and Risdon (1981) proposed a "big bang" theory for the origin of scars after infant pyelonephritis. They observed that most of the scarring to which the kidney is ultimately susceptible occurs after the initial bout of pyelonephritis and that further scarring in the absence of repeated pyelonephritic episodes is unlikely to occur. Consequently, the assumption is that little change in the initial scarring pattern is to be expected in follow-up scintigraphic imaging. However, the uncertainties introduced by such factors as (1) the weakly substantiated assumption that a relatively greater scarring propensity exists in younger kidneys, (2) the reports of new follow-up scarring in the landmark reflux studies (see later discussion), (3) the failure to differentiate between postpyelonephritic imaging defects resulting from infection versus intrinsic developmental dysmorphism associated with reflux, (4) the changing appearance of such imaging defects with renal growth over time, and (5) the limited ability to compare disparate imaging modalities in the reflux literature (urograms vs. nuclear scans) together must challenge the notion that the greatest postinfection parenchymal loss occurs after the first infection.

KEY POINTS: CORTICAL DEFECTS

- Sterile reflux is considered benign.
- The youngest patients are at greatest risk for postpyelonephritic renal scarring.
- Most parenchymal abnormalities are detected after the first episode of pyelonephritis.
- Somatic growth is an accurate reflection of renal cortical integrity.

Papillary Anatomy

Another factor governing renal susceptibility to scarring is the configuration of the papillae as their ducts open to the calyces. Papillae with a concave architecture (compound papillae) present their ducts at right angles, whereas more convex papillae possess ducts that end obliquely, producing a valvular effect that guards against backflow of urine into the medullary collecting ducts (Fig. 137-11). The more polar calyces are composed preferentially of compound papillae compared with the middle calyces. The former are more commonly the site of intrarenal reflux (reflux into the ducts) and are the prime regions of susceptibility to scarring. Furthermore, necropsy studies have determined that reflux into compound papillae occurs at lower pressures than into simple papillae (Funston and Cremin, 1978). Intrarenal reflux can occur with as little as 2 mm Hg pressure in the neonate (Fig. 137-12). By 1 year of age, the pressure required is one order of magnitude greater (Funston and Cremin, 1978) and helps explain the relative infrequency of intrarenal reflux in older children.

Figure 137-11. Papillary configuration in intrarenal reflux. A convex papilla (right) does not reflux because the crescentic or slitlike openings of its collecting ducts open obliquely onto the papilla. In contrast, a concave (left) or flat papilla refluxes because its collecting ducts open at right angles onto a flat papilla. (From Ransley PG, Risdon RA. Reflux and renal scarring. *Br J Radiol* 1978;14[Suppl.]:1.)

Host Susceptibility and Response

Please see the Expert Consult website for details.

Hypertension

VUR has long been held as the primary cause of significant hypertension in children. Arterial derangements in the renin-angiotensin system and sodium-potassium adenosine triphosphatase activity (Goonasekera and Dillon, 1998) may be involved, though the precise pathophysiologic process is not clear. Although methodologic flaws (Farnham et al, 2005) taint many studies of hypertension in the pediatric urology population, one study using continuous ambulatory blood pressure monitoring revealed some correlation between progression to hypertension and more severe reflux nephropathy in children (Lama et al, 2003). A recent adult review of 157 patients with hypertension, but no evidence of abnormal renal parameters, discovered by cystography that latent VUR was present in 20% of the subjects, demonstrating that a significant association between reflux and hypertension exists in adulthood (Barai et al, 2004). The striking association between VUR diagnosed for the first time only in adulthood and arterial hypertension continues to underscore the importance of remaining vigilant about untreated infections in the reflux population (Kohler et al, 1997). Nevertheless, it remains unclear whether it is the nephropathy associated with postinfection scarring, congenital dysmorphism associated with reflux, or some combination of both that predisposes to hypertension (Wolfish et al, 1993). This latter observation questions, then, whether prevention of postinfection scarring per se in the management of VUR will specifically help offset future hypertensive risk in cases in which congenital renal dysmorphisms are already present. There is obvious potential for the cause of reflux-associated hypertension to rest with deranged renal microvascular mechanisms associated with parenchymal defects. This suggests that successful correction of reflux alone is unlikely to ameliorate blood pressure (Wallace et al, 1978). Indeed, removal of renal segments verified by selective renal vein sampling of arteriolar or segmental vessel renin levels has provided durable normalization of blood pressure in carefully selected patients (Tash et al, 2003). On occasion, complete removal of a small unilateral congenitally dysmorphic or globally scarred and shrunken kidney also may correct renovascular hypertension (Dillon and Smellie, 1984), because such kidneys are clearly not amenable to partial nephrectomy for any discrete segment.

Renal Growth

Several studies have attempted to demonstrate that correction of reflux will restore retarded renal growth associated with reflux, particularly when the growth defect is in a unilaterally affected kidney. However, reflux correction is a poor predictor of catch-up growth in such kidneys (Hagberg et al, 1984; Shimada et al, 1988). A significant factor governing growth of an ipsilateral kidney is the function of its contralateral mate. Although forestalling infection in the presence of VUR will maintain the normal trajectory of renal growth in most cases (Smellie et al, 1981a), it must be remembered that compensatory hypertrophy of the contralateral kidney will magnify the perceived impact of infection on renal growth because the contralateral developing kidney will assume the required renal function whenever the ipsilateral kidney is unable to contribute optimally to function. When reflux correction has been associated with improved renal growth, it is likely this is due to removal of the propensity for ascending infection rather than the elimination of the reflux per se (Willscher et al, 1976a, 1976b).

Renal Failure and Somatic Growth

Today, renal failure resulting from primary VUR-associated infection should be an anachronism, although it is still seen. This is largely due to the virtual paradigm shift in reflux management championed by Smellie and colleagues during their pivotal studies of reflux and infection in children during the 1970s and 1980s. Over the past 30 years, chronic pyelonephritis as a primary cause of end-stage renal disease has fallen from 15% to 25% (Advisory Committee to the Renal Transplant Registry, 1975) to less than 2% (North American Pediatric Renal Transplant Cooperative Study, 2004). Reflux nephropathy in all its forms, however, was the fourth most common primary diagnosis in nonblack pediatric transplant recipients (North American Pediatric Renal Transplant Cooperative Study, 2004). The medical renal disease (Hinchliffe et al, 1994) that accompanies renal scarring can include hyperfiltration, concentrating defects, proteinuria, microalbuminuria (Lama et al, 1997), renal tubular acidosis (Guizar et al, 1996), and increased fractional excretion of sodium and magnesium. Although all of these parameters are likely the direct result of tubular and parenchymal damage or dysmorphism, concentrating defects and increased concentrations of tubular enzymes (Carr et al, 1991) have been reported in the presence of sterile reflux, independent of any history of infection per se (Walker et al, 1973). The concentrating defect is proportional to reflux grade and improves after reflux cessation. These observations have suggested that a relative flow resistance may be created by retrograde nature of reflux and raises the possibility of a functionally obstructive parameter in reflux pathogenesis. However, the precise relationship between antegrade flow, retrograde flow, and bladder dynamics in this theoretic mechanism has not been more fully articulated.

One of the best global parameters of renal function in children is the somatic growth curve. Many children with VUR fall below the normal age-adjusted growth curve, particularly in patients with bilateral reflux and some degree of renal damage. Furthermore, successful suppression of pyelonephritis through either medical prevention of infection or surgical correction of reflux itself can result in catch-up growth, both for height and weight (Polito et al, 1996, 1997). Although a clear superiority has yet to be demonstrated between medical and surgical therapy to affect growth improvement or subsequent renal scarring after an initial pyelonephritic insult, surgical correction of reflux can benefit somatic growth when recurrent breakthrough infection indicates failure of antibiotic prophylaxis (Sutton and Atwell, 1989).

ASSOCIATED ANOMALIES AND CONDITIONS

Ureteropelvic Junction Obstruction

VUR and UPJO are two of the most common pathologic conditions in pediatric urology. Thus it is not unusual that these two conditions

Bacteria possess phenotypes that provide infective advantage when exposed to the lumen of the urinary tract. Chief among these is the ability to adhere to uroepithelium. Adherence is mediated by interaction between specific molecules or ligands located on bacterial fimbriae and specific receptors on host uroepithelial cells. A full discussion of the mechanism of action of uropathogenic bacteria is found elsewhere in the text. Once bacteria bind to host epithelium, specific biologic responses are activated in both the microorganism and host cell. Bacterial responses are designed to facilitate their survival and proliferation, as well as inhibit host defenses. These include release of endotoxin and reduction of ureteral peristalsis, which may lead to urinary stasis and reduced antegrade flow of urine. The host inflammatory response perpetuates the classic symptoms of UTI. Although a more systematic understanding of bacterial-host interactions in the propensity for reflux-associated renal scarring is not yet available, it appears that bacteria responsible for postpyelonephritic scars in the presence of reflux often express fewer than three virulence factors (Lomberg et al, 1984). Ironically, then, less virulent bacteria are most often sufficient to produce scarring in the presence of reflux.

Nonhematogenous bacterial access to the urinary tract rests essentially with periurethral organisms. Thus the type and number of vaginal and preputial organisms will determine individual propensity for bladder colonization. Local factors such as hygiene and bowel habits also will influence the bacterial load presented to the perineal surface from the intestinal tract, the latter being the principal repository for organisms that infect the urinary tract. The functional diversity of the host receptors for bacterial adherence also plays a role in the success or failure of bacteria to gain entry to the bladder. In one study, girls with recurrent UTI harbored far heavier periurethral colonization than a control group of girls who were infection free, suggesting a variation in the function of antibacterial defenses in susceptible females (Bollgren and Winberg, 1976a). Furthermore, such factors may exhibit both gender- and age-related dimorphism (Bollgren and Winberg, 1976a). The great majority of UTIs in both sexes younger than 6 months of age is confined to uncircumcised boys (Rushon et al, 1992) and is consistent with the observation that *Escherichia coli* colonization is dense in infant boys but sparse in girls (Bollgren and Winberg, 1976b).

Perhaps the greatest tangible factor in promoting susceptibility to UTI is urinary dwell time. The postvoid urine volume is traditionally singled out as being suspect in providing sanctuary for ascending urethral organisms. Perhaps more important, however, is the overall dwell time between voids, which provides the greatest advantage to bacterial proliferation. **When the average doubling time for *E. coli* is measured in minutes, it is self-evident that a quantity of microorganisms sufficient for clinical infection can easily incubate exponentially in a bladder that is not emptied for several hours.**

Advances also have been made in understanding the renal epithelial response to pathogens. The classic components of the innate immune response to infection include activation of the complement system; recruitment of neutrophils and macrophages with scavenging ability; and production of a variety of cytokines, chemokines, and defensins (antimicrobial peptides). One family of receptors, the Toll-like receptors (TLRs), responds to highly constant antigens expressed in bacteria (Chowdhury et al, 2004). The best studied of these, TLR4, detects lipopolysaccharide (LPS). A breakthrough in understanding renal infection came with the demonstration that mutations encoding the *TLR4* gene were responsible for LPS hyporesponsiveness (Hoshino et al, 1999). Nevertheless, molecules accessory to TLR4 are important to its response to LPS. Similarly, molecules such as CXCR1 and CXCR2 are receptors for interleukin-8, the principal renal epithelial secreted chemokine responsible for neutrophil migration (Godaly et al, 2000). Deficiencies of CXCR expression and function may underlie human susceptibility to pyelonephritis (Freundt et al, 2000, 2001). Such advances placed into the context of VUR provide interesting and powerful opportunities to modify the natural history of the condition.

As well as orchestrating the assembly of the phagosome for bacterial clearance, **the fallout of these renal epithelial processes that is the inflammatory response leads to local tissue damage and scarring.** Hallmarks of the response include capillary congestion, ischemia and reperfusion injury, and free oxygen radical and inflammatory cytokine release (Roberts, 1990, 1992). Microabscess formation later coalesces into scar tissue typical of the histologic changes of chronic pyelonephritis (Roberts, 1995). Although limiting the inflammatory response to reduce scarring may appear logical, no specific pyelonephritis anti-inflammatory pharmacotherapy is yet available. Traditional nonspecific anti-inflammatory agents, both steroidal and nonsteroidal, are not currently indicated in the treatment of pyelonephritis; in their current formulations the latter poses a threat to renal function (Schaller and Kaplan, 1998). Nevertheless, the concept has been demonstrated experimentally in animals (Huang et al, 1999). A full understanding of the specific pathways involved in reflux-associated pyelonephritis could provide key strategies to limiting specific renal inflammatory fallout without limiting bacterial clearance. Until then, antimicrobial therapy instituted in a timely fashion, usually within 24 to 48 hours, is the single most effective pharmacologic strategy to date to limit the scarring consequences of pyelonephritis in both young and older children (Ransley and Risdon, 1981; Smellie et al, 1985).

coexist. Whether the concomitant presence of these two conditions is a random event or is causally related remains unclear. It has been speculated that a developmental ureteric bud anomaly may be responsible for the imperfect formation of both the UVJ and the UPJ (Bomalaski et al, 1997a).

The incidence of VUR associated with UPJO ranges from 9% to 18% (Lebowitz and Blickman, 1983; Maizels et al, 1984; Hollowell et al, 1989; Bomalaski et al, 1997a; Kim et al, 2001). When the two conditions were primarily present, most of the patients in these studies had reflux that was coincidentally discovered, was of low grade, and resolved spontaneously with time. Such patients typically exhibited a significant discrepancy between the minimal degree of ureteral dilation and the significantly dilated renal pelvis. Thus the apparent grade of reflux may be overestimated, and management decisions based on the grade of reflux are inaccurate at best.

Conversely, the incidence of UPJO in patients with reflux ranges from 0.75% to 3.6% (Lebowitz and Blickman, 1983; Bomalaski et al, 1997a), with high-grade reflux being five times more likely to be associated with UPJO than lower grades of reflux (Lebowitz and Blickman, 1983; Bomalaski et al, 1997a). Indeed, in one study of children with reflux and hydronephrosis, 50% of high-grade sonographic hydronephrosis, commonly associated with the highest grades of reflux, showed an obstructive pattern on furosemide (Lasix) scintigraphy (Stauss et al, 2003).

Three radiology signs might suggest the existence of UPJO in the setting of reflux. First, if the pelvis shows little or no filling, while the ureter is dilated by contrast, this may indicate a point of kinking secondary to reflux or from a primary UPJO (Fig. 137-13). Second, contrast that does enter the pelvis may be poorly visualized because of dilution in a large pelvic volume and exhibits a markedly reduced radiodensity compared with the ureter or bladder. Finally, a large

Figure 137-13. Reflux and ureteropelvic junction (UPJ) obstruction. A, Significant reflux fills the left ureter to the level of the UPJ. Minimal filling of the pelvis can be a sign of obstruction at this level. B, In a different patient, reflux is seen as the bladder fills. C, Significant kinking of the UPJ occurs with voiding.

pelvis that fails to exhibit prompt drainage but retains contrast is also suggestive of UPJO.

Radiographic studies of UPJO associated with VUR may indicate true anatomic obstruction or simply dilation associated with pelvic-ureteral dilation from higher grades of reflux. [Hollowell and colleagues \(1989\)](#) referred to three clinical categories of concomitant obstruction and reflux. Group 1 had primary UPJO and incidental low-grade reflux, and group 2 had secondary UPJO from high-grade reflux. These two groups represent true anatomic obstruction for which pyeloplasty is recommended. Group 3 represents only significant dilation of the upper tracts, which is confirmed by documenting good drainage images by cystography or renal scintigraphy.

The cause of secondary UPJO is unclear. Several factors are thought to predispose or even aggravate a potential narrowing at the level of the UPJ. High-grade reflux may result in kinking of the upper ureter and adjacent pelvic junction. The chronic effects of reflux also may stretch the renal pelvis so that atonicity and an inability to propel urine through the UPJ may occur ([Whitaker, 1973](#)). In the setting of UTI propagated to the upper tracts by reflux, inflammation and ureteritis also can contribute to transient or chronic obstruction at the UPJ.

The convergence of two ureteral anomalies in the same patient raises additional management questions in the situation in which treatment of one anomaly may affect the natural history of the other. Nevertheless, the guiding therapeutic principle is the preservation of renal function. Although sterile reflux may be observed, obstruction even in the absence of infection may jeopardize renal function. Therefore, in the presence of reflux, if scintigraphy with catheter drainage confirms obstruction, pyeloplasty should be performed. The secondary insult to the UPJ from reflux is an evolving process that cannot be efficiently or adequately corrected by surgical repair of the reflux itself. Furthermore, reflux correction alone risks amplifying upper tract dilation during the phase of postoperative edema in the lower ureter, as well as risks introducing infection to a renal pelvis still harboring obstruction at the UPJ.

The simultaneous open correction of UPJO and reflux has always raised a concern over surgical manipulation of both the upper and lower ureter at the same time, as well as its potential negative impact on ureteral vascularity. However, the advent of endoscopic injection raises the possibility of correcting reflux at the time of pyeloplasty for secondary or primary UPJO. The indications for reflux correction are being re-evaluated since the advent of endoscopic therapy and are discussed in the later section on endoscopic management.

Ureteral Duplication

VUR is the most common abnormality associated with complete ureteral duplications. The embryologic origin of the duplicated ureter supports the observation that reflux occurs most commonly into the lower pole. This relationship is based on the studies of [Weigert \(1877\)](#) and [Meyer \(1946\)](#), who documented the more lateral and proximal insertion of the lower pole ureter associated with a shorter intramural ureter at the UVJ ([Fig. 137-14](#) on the Expert Consult website).

The incidence of reflux is increased in patients with complete ureteral duplication ([Privett et al, 1976](#)). Earlier studies provide a limited view of whether reflux in a duplex moiety carries increased patient risk because of lack of control groups, arbitrary patient selection, and short follow-up. There has been some tendency to correct reflux on the basis of the existence of the duplication anomaly itself. Even in the absence of obstruction from a ureterocele or ureteral ectopia, duplication with low-grade reflux may take longer to resolve than in single-system reflux ([Estrada et al, 2009](#)), though it carries no heightened risk for increasing grade, breakthrough infection, or scarring ([Ben-Ami et al, 1989](#); [Husmann and Allen, 1991](#)). The most recent series supports this finding in low-grade reflux but notes that high-grade reflux into lower pole ureters in females is more prone to breakthrough infection and scarring and therefore may warrant more aggressive management ([Afshar, 2005](#); [Estrada et al, 2009](#)).

Bladder Diverticula

A full discussion of bladder diverticula is found elsewhere in the text. The outpouching of mucosa between detrusor muscle bundles, which lacks any true muscle backing itself, commonly defining a bladder diverticulum, has the theoretic potential to affect the natural history of VUR in two ways. Most commonly, if the UVJ is distorted by the so-called paraureteral diverticulum, which shares an anatomic point of origin at or near the UVJ, it is theoretically possible that the configuration of the diverticulum could compromise the antireflux configuration of the UVJ to cause reflux ([Fig. 137-15](#) on the Expert Consult website). Second, and more rarely, a large paraureteral diverticulum could expand within the Waldeyer fascia to cause ureteral obstruction or project forward into the bladder to obstruct the bladder outlet, much as a ureterocele, and incite secondary reflux ([Boechat and Lebowitz, 1978](#)). Although the latter would require cystoscopic confirmation, neither cystoscopy nor imaging is predictive of whether paraureteral diverticula truly compromise the resolution of reflux, as has been commonly believed. [Hutch \(1961\)](#) was the first to recognize that bladder diverticula were congenital abnormalities that occurred primarily in smooth-walled normal bladders in children. A 40-year review of the literature from 1966 to 2004 fails to provide any objective case-control or cohort studies to support the routine repair of reflux where the sole indication was the presence of a paraureteral or Hutch diverticulum. However, a contemporary retrospective cohort analysis of 84 patients with paraureteral diverticula and reflux showed no significant difference in spontaneous resolution rates (60%, 39%, and 22% for grades 1 to 2, 3, and 4 to 5 reflux with paraureteral diverticulum vs. 52%, 28%, and 33% in a matched control group of 95 patients with reflux without diverticulum). Rates of UTI and scarring were similar in both groups. Multivariate analysis revealed reflux grade to be the only predictor of resolution in both groups ([Afshar, 2005](#)). Thus reflux associated with paraureteral diverticula resolves at rates similar to that of primary reflux and should be managed according to the prevailing indications for the reflux itself, irrespective of the diverticulum. However, when a refluxing ureter enters a diverticulum, the latter is no longer paraureteral. With no muscular support to the UVJ, reflux is not expected to resolve. In a given patient, indications for repair require the combined consideration of the potential impact of unresolved reflux, if any, along with whether the diverticulum itself is of sufficient size or conformation to incite complications.

Renal Anomalies

By definition, primary reflux represents a dysfunction of the UVJ. Because the development of both the UVJ and the kidney itself are linked to the origin and fate of the ureteral bud, it is reasonable to consider the existence of reflux whenever an anomaly of renal form or number is present. The cardinal renal anomalies associated with reflux are multicystic dysplastic kidney (MCDK) and renal agenesis, and the presence of either condition mandates a VCUG. In the largest series to date, 75 patients with MCDK showed a prevalence of contralateral reflux of 26% (19 patients) and half of these were low grade (1 to 2) ([Miller et al, 2004](#)). Spontaneous resolution occurred in a mean of 4.4 years, regardless of grade. Only one patient had reflux corrected surgically. In a small series of ureteral ectopia, one patient with MCDK had the contralateral ureter enter into the ductus deferens ([Wunsch et al, 2000](#)), further underscoring the importance of documenting the contralateral kidney's ureteral conformation in patients with MCDK. Although contralateral renal growth often displays compensatory hypertrophy, one study observed somewhat less compensatory hypertrophy by 1 year of age ([Zerin and Leiser, 1998](#)) than may be expected if contralateral reflux is absent (5.1 vs. 6.2 cm median renal lengths, $P < .001$).

Renal agenesis is associated with an even higher prevalence of contralateral VUR. In a retrospective study of 46 children with solitary renal agenesis, the rate of contralateral renal pathology was 46%. VUR was by far the most common contralateral defect (28%) ([Cascio et al, 1999](#)) with UVJ and UPJO seen in 11% and 7%,

Figure 137-14. Reflux into both ureters of a complete duplication, as shown here, is less common than reflux into the lower pole ureter alone.

Figure 137-15. A, Schematic representation of a bladder diverticulum (2). A small amount of mucosa initially herniates through a congenital defect in the bladder musculature. The defect enlarges with voiding. Finally, the ureteric orifice (1) is incorporated into the diverticulum. B, Reflux into a right-sided paraureteral diverticulum and ureter seen on voiding cystography. (A, From Hernanz-Schulman M, Lebowitz RL. The elusiveness and importance of bladder diverticula in children. *Pediatr Radiol* 1995;15:399–402.)

respectively. Both UPJ and reflux were present in 1 patient. In another study, 19 cases of contralateral reflux were observed in 51 patients with ipsilateral renal agenesis (Song et al, 1995). Reflux repair or persistence was documented in 9 and 7 patients, respectively, with spontaneous resolution observed in only 3 patients. Whether renal agenesis represents one extreme on a continuum that includes MCDK is unclear. Nevertheless, these data suggest that contralateral reflux associated with renal agenesis may show less tendency to spontaneous resolution than that associated with MCDK.

Megacystis-Megaureter Association

Massive bilateral VUR can cause a gradual remodeling of the entire upper urinary tract. The gross inefficiency of the bladder that expels urine to both the exterior and the upper tracts results in gradual bladder dilation as the refluxed urine returns to the bladder. This perpetuates marked ureteral dilation, leading to the radiographic appearance of massive hydroureter and a thin-walled enlarged bladder (Burbige et al, 1984). The phenomenon is referred to as the megacystis-megaureter association or syndrome. This configuration is even discernable in utero (Mandell et al, 1992). It is more frequent in males, and the differentiation from posterior valves is crucial (Kaefer et al, 1997). Although the latter is due to an obstructive lesion, megacystis-megaureter is a nonobstructive condition akin to cardiac dilation by regurgitation from incompetent valves. Voiding studies will readily demonstrate an open posterior urethra and differentiate megacystis-megaureter from posterior valves or prune-belly syndrome. The persistent large residual urine volume is a significant risk factor for recurrent UTI. Vesicostomy can temporize by eliminating the residual urine volume and establishing safe drainage of the upper tracts until ureteral reimplantation can be performed. Given the propensity for reflux to exacerbate the effects of bacteriuria and the fact that UVJ dysfunction is the primary factor perpetuating the syndrome, surgical correction for the reflux is indicated. Treatments aimed at improving an already patent bladder outlet are contraindicated, risk infection, and fail to correct the primary cause. A period of bladder rehabilitation by strict attention to emptying in the postoperative period (Koefoot et al, 1981) usually will result in a return to normal bladder volume and contractile behavior. This suggests that potentially normal underlying bladder physiology can be realized if the propensity for reflux is corrected.

Other Anomalies

VUR also has been described in association with a number of congenital conditions and syndromes. No precise common genetic insult has been determined to explain such associations. A complete survey of the Online Mendelian Inheritance in Man Database developed by Johns Hopkins University, maintained by the National Center of Biotechnology Information, reveals more than 40 different syndromes in which VUR has been described (<http://www.ncbi.nlm.nih.gov/Omim/getmap.cgi?193000>). These include the VACTERL association (Vertebral, Anal, Cardiac, TracheoEsophageal, Renal, and Limb anomalies), CHARGE syndrome (Coloboma, Heart disease, Atresia choanae, Retarded development, Genital hypoplasia, and Ear anomalies), and imperforate anus. In cases in which VUR is anticipated, a VCUG is the initial study of choice to disclose both dysfunction at the UVJ and overall bladder and bladder outlet anatomy.

Pregnancy and Reflux

The morphology of the urinary tract is altered with the onset of pregnancy and increases throughout gestation (Beydoun, 1985). Bladder tone decreases because of edema and hyperemia, changes that predispose the patient to bacteriuria. In addition, urine volume increases in the upper collecting system as the physiologic dilation of pregnancy evolves. The slower drainage that results can enhance the growth of organisms and increase the

propensity to develop pyelonephritis. It seems logical to assume that during pregnancy the presence of VUR in a system already prone to bacteriuria would lead to increased morbidity. A number of studies have been conducted to examine this relationship.

The presence of active reflux appears to present a risk factor for the affected mother. In 1958, Hutch described a higher incidence of pyelonephritis during pregnancy in 23 women with a history of reflux and recurrent bacteriuria (Hutch, 1952, 1961). Heidrick and colleagues (1967) evaluated 321 women with cystography either during the last trimester or within 30 hours after delivery. The incidence of pyelonephritis was 33% in women with reflux compared with less than 5% in women without reflux. Finally, cystograms performed 4 to 6 months postpartum in 100 women with a history of asymptomatic bacteriuria during pregnancy showed reflux in 21%. Bacteriuria was easier to clear in patients without reflux (67%) than in those with reflux (33%) (Williams and Hulme-Moir, 1970).

Maternal history also becomes a factor if past reflux, renal scarring, or a tendency to UTIs is included. Martinell and colleagues (1990) compared the outcome of pregnancy in matched controls with that in 41 women with and without renal scarring after childhood UTIs. They found that women with a history of prior infections had a high incidence of bacteriuria during pregnancy, whereas those with renal scarring and persistent reflux were more prone to develop acute pyelonephritis. In a similar study, the outcome of pregnancy was assessed in 88 women with previous bacteriuria. Women with known scars had a 3.3-fold increased incidence of hypertension, a 7.6-fold increased risk for preeclampsia, and a higher rate of obstetric interventions. Women with normal kidneys and reflux also had an increased risk for hypertension during the last trimester (McGladdery et al, 1992). Pregnant women with bilateral renal scars were also shown to have a higher incidence of preeclampsia than those with unilateral scarring (24% vs. 7%, respectively) (El-Khatib et al, 1994), and those with creatinine elevation are also at risk (Jungers et al, 1987). In a large study of 158 women with reflux nephropathy, pregnancy was uneventful in patients with normal blood pressure and renal function, whereas the risks for fetal demise and accelerated maternal renal disease were increased in women with impaired renal function (Jungers, 1996).

The implications of reimplantation surgery were studied by Austenfeld and Snow (1988), who found an increased risk for UTI and fetal loss in 31 women who had undergone ureteral reimplantation as children, despite correction of the anomaly. In a follow-up study comparing these patients with a new cohort of historical controls, women with UTIs and reflux who underwent reimplantation (suggesting an initially higher degree of reflux and increased renal scarring) were still at significant risk for UTI during pregnancy (Mansfield et al, 1995). However, they were not at a higher risk for miscarriage than the general population. In a larger study of 77 pregnancies in 41 women whose ureters had been reimplanted, Bukowski (1998) and colleagues reported that the incidence of pyelonephritis during pregnancy was slightly higher than in the general population but that the fetus and mother were at significant risk when renal scarring or hypertension was present. Although these studies may at first suggest a limited benefit to reimplantation during a subsequent pregnancy, several factors must be borne in mind. None of these studies document any associated BBD in these women, which may have existed in childhood and continued unrecognized into the fertility years. Also, bladder dynamics change during pregnancy as a result of increasing uterine size. Although it is assumed that reflux remains absent during pregnancy after correction in childhood, radiologic verification that the surgically corrected UVJ remains competent (reflux free) is not feasible and such data are not available. Finally, it is not known whether formerly refluxing renal units in such adult patients carry a latent predisposition or heightened susceptibility to pyelonephritis during the pregnancy as a consequence of previous postinfection damage during childhood and/or any inherent reflux-associated dysmorphism, both of which would persist despite surgery at the bladder level. Nevertheless, in keeping with the more recent emphasis on preexisting renal status when considering reflux management, at least one meta-analysis of the

significance of a pregnancy and reflux association also suggests that the presence of renal scarring, and not the presence or absence of reflux, is the principal factor driving morbidity during pregnancy in such women (Hollowell, 2008). When combined with the known physiologic renal and bladder changes during pregnancy, it is reasonable to speculate that such kidneys may carry a heightened predisposition to pyelonephritis.

In summary, the majority of studies examining the effects of VUR on pregnancy suggest that women with a history of reflux have increased morbidity during pregnancy because of infection-related complications, whether the reflux has been corrected or not. **Women with hypertension and an element of renal failure are particularly at risk.** Those with uncorrected reflux appear to be particularly at risk and should have their reflux corrected before pregnancy to minimize maternal and fetal morbidity. The morbidity during pregnancy of women with persistent reflux without renal scarring remains poorly defined, but the tendency to UTI seems to be increased. Because of the difficulty in predicting an outcome for this subset of patients, most clinicians recommend surgical correction for girls with reflux that persists beyond puberty, although there has been a trend toward discontinuation of prophylactic antibiotics in older girls with active reflux. Long-term follow-up studies of these patients through puberty are unavailable (see later discussion).

KEY POINTS: PREGNANCY AND REFLUX

- Physiologic changes in the ureter and bladder during pregnancy may influence the propensity for reflux-associated pyelonephritis in pregnant patients with reflux.
- In the absence of definitive studies to the contrary, correction of reflux may be considered before pregnancy.

NATURAL HISTORY AND MANAGEMENT

Spontaneous Resolution

The one feature of VUR that provides the greatest relief to parents and caregivers but at the same time creates confusion in reflux study design and literature interpretation is spontaneous resolution. Indeed, the basis of contemporary medical therapy is predicated on an expected rate of spontaneous resolution. At birth, the probability of spontaneous resolution of primary reflux is roughly inversely proportional to the initial grade. If a patient is encountered at a later age, resolution from any point in time forward will depend on initial grade of reflux, if it is known, and age at presentation. For example, unilateral grade 3 reflux at birth should resolve in 70% of cases by age 5. However, if a 6-year-old with normal bladder function presents with grade 3 reflux, it is much less likely to resolve. Given a growing tendency among some clinicians to reassess females for persistent reflux and possible endoscopic correction after a holiday period without follow-up (between 5 years and the teenage years), it is possible new information remains to be learned about reflux resolution. Reflux likely resolves spontaneously as a result of remodeling of the UVJ over time, with progressive elongation and consolidation of the intravesical ureter and antireflux mechanism, as well as stabilization of bladder dynamics. Conversely, failure of the latter likely accounts for reflux persistence beyond the statistical norms in many patients. Indeed, inability to strictly understand bladder dynamics may have skewed earlier determinations of absolute reflux resolution rates but in doing so provided a real-world picture of spontaneous resolution.

Resolution by Grade

Most cases of low-grade reflux (grade 1 and 2) will resolve. Several studies have documented this high rate of spontaneous resolution. However, the variance in reported resolution rates for low-grade reflux was 63% of grade 2 (Duckett, 1983), 80% of grade 2 (Arant,

1992), and 85% of grade 2 (Edwards et al, 1977). This belies the fact that lower urinary tract dynamics may also play a role in mitigating spontaneous resolution.

Grade 3 reflux will resolve in approximately 50% of cases (Duckett, 1983; McLorie et al, 1990). Very few cases of higher grade reflux (grades 4 and 5, and bilateral grade 3) will resolve spontaneously. Analyses from several sources, including the International Reflux Study in Children, support a uniformly low prevalence of resolved high-grade reflux with no more than 25% (Weiss et al, 1992b) and as little as 9% (Skoog et al, 1987) of patients demonstrating spontaneous resolution. It is possible no real difference exists in resolution rates in high-grade reflux (Tamminen-Mobius et al, 1992). Considering the fact that any given reflux grade is assigned on the basis of a dynamic voiding study, the possibility for variability by at least one grade, especially in assigning higher grades to reflux, is quite real. Thus attempting to discriminate true differences in resolution rates for grades 3 and higher reflux may not be particularly clinically relevant.

Resolution by Age

The age at which reflux begins or is first encountered will play a more potent role in the management of the patient with reflux than the grade itself. It is self-evident that if reflux is a congenital disorder with an inherent tendency to resolve spontaneously over time, it will (1) be most prevalent in neonates and young children, and (2) demonstrate the greatest tendency to resolve in this group. Conversely, in any analysis, if reflux is truly primary, is encountered in an older child, and has been present since birth, it already has demonstrated a propensity to persist and therefore is self-selected for reflux, which is unlikely to resolve (Skoog et al, 1987). The 1997 AUA guidelines data provide a synthesis of large numbers and reasonable statistical estimates of resolution rates segregated by age and grade (Elder et al, 1997) (Fig. 137-16). Interpretation of more recent follow-up studies (Connolly et al, 2001) suggest that diagnosis at age 5, as well as in infancy, is associated with a similar resolution rate (20% per year), regardless of age. However, as stated at the outset, it must be remembered that resolution 5 years after age 5 implies reflux has required 10 years to resolve versus resolution 5 years after birth. Moreover, the observation by McLorie and colleagues (1990) that high-grade reflux in patients presenting after birth showed no difference in resolution rates between subjects younger and older than 1 year of age may reflect the generally poor resolution rate of high-grade reflux to begin with. Thus persistence in early life will imply persistence when older. These principles likely underlie the observation that when reflux resolves, it often does so within the first few years of life. The study by Skoog and colleagues (1987) observed that 30% to 35% of subjects resolved their reflux each year. Reflux in younger patients (<12 months old) resolved more quickly (1.44 vs. 1.85 years, $P < .02$), with grade 3 requiring slightly more time than grade 2 to resolve (1.56 vs. 1.97 years, $P < .04$).

The traditional period of observation for resolution is 5 years, probably because the greatest proportion of growth and anatomic remodeling of the UVJ is complete. In the study by McLorie and coworkers (1990), 92% of resolved grade 3 reflux occurred within 4 years. There is a tendency to ascribe a benefit to the observation of interval reduction in grade. Such a finding could herald progression to resolution, but in the end it still carries the same risk for escalating a UTI to pyelonephritis and so should be interpreted with caution when counseling families. The resolution rates for VUR followed into the teenage and adult years remain unknown. **Clearly then, what constitutes reflux resolution depends on the period over which resolution is sought.**

Principles of Management

The medical and surgical therapy for reflux has purported to offer similar benefit to patients (Table 137-6 on the Expert Consult website). This has fueled the debate between fundamental choices of therapy for decades. The tension embedded in decision making

B, Percent chance of persistence of grade 3 reflux by age for 1 to 5 years after initial evaluation. (From American Urological Association. Report on the management of vesicoureteral reflux in children. Baltimore: American Urological Association, Pediatric Vesicoureteral Reflux Clinical Guidelines Panel; 1997.)

for reflux management stems from the almost perfect results attainable by surgical correction of reflux, now commonly successful in more than 98% of cases. However, traditional practice in reflux management has held that the end does not justify the means: Reflux correction is not indicated merely because it can be corrected easily and reliably. As stated earlier, almost 80% of low-grade and half of grade 3 reflux will resolve spontaneously. Walker (1994) summarized the essential tenets of reflux management as follows:

1. Spontaneous resolution of reflux is very common.
2. High-grade reflux is less likely to resolve spontaneously.
3. Sterile reflux is benign.
4. Extended use of prophylactic antibiotics is benign.
5. Success of (open) surgical correction is very high.

Rather than providing strict guidelines for treatment, these principles provide ample room to individualize treatment on the basis of the particular preferences and tolerances of physicians, families, and patients for the various burdens each of the principles entails. The classic approach has been to offer daily low-dose prophylactic antibiotic suppression of infections as the first line of treatment under the principle that every case of reflux should be offered time to resolve spontaneously, despite grade. Clearly, age at presentation and grade will factor into predicting when and if resolution is likely to occur. In addition, in patients diagnosed after

one or more episodes of pyelonephritis, the presence of scarring on renal scintigraphy may temper a decision for extended prophylaxis and observation, particularly if scarring is extensive, the reflux is high grade, renal function is already globally depressed, or congenital dysmorphism of one or both kidneys is present. In such cases, tolerance for yet another infection despite the presence of prophylaxis may be low, or simple disquiet with the notion of ongoing reflux may invite strong consideration for reflux correction.

As stated previously, it is not clear how long to wait for reflux resolution in the individual patient. In newborn patients, it is reasonable to wait until approximately 5 years of age assuming no intercurrent breakthrough infections occur. Beyond this age, it is commonly believed that the kidneys become less prone to scarring after pyelonephritis (Olbing et al, 2003), although the previously mentioned limitations in the interpretation of imaging inherent in the reflux literature should be remembered. Thus some practitioners are withdrawing prophylaxis as the child approaches the age of 5. After this age, boys with asymptomatic reflux will require little or no formal follow-up as long as lifelong attention to good bladder habits is reinforced, and they are counseled to seek prompt medical attention if a pyelonephritis were to occur in the future, as well as reassessment of their reflux status. Nevertheless, disagreement would remain as to whether to correct asymptomatic bilateral high-grade reflux with normal renal parenchyma and function in an older boy despite the thought that sterile reflux is benign. Girls have traditionally undergone open surgical correction, even for asymptomatic reflux that fails to resolve by the age of 5, on the premise that it will reduce maternal and fetal morbidity during a future pregnancy. Using the rationale of antibiotic withdrawal in the older child, one study demonstrated that less than 10% of patients will subsequently develop recurrent febrile UTIs mandating surgical correction of reflux (Cooper et al, 2000), albeit with limited clinical follow-up and using only ultrasound imaging to assess renal health. Clinical guidelines for reflux management in children are presented in Table 137-7 on the Expert Consult website.

Adult patients who present with nonobstructive flank pain, febrile UTIs, or pyelonephritis and are found to have VUR have traditionally been offered antireflux surgery. Endoscopic correction of uncomplicated adult reflux also should be possible (Arce et al, 2009).

Emerging Role for Endoscopic Correction of Reflux

Please see the Expert Consult website for details.

Medical Management: Watchful Waiting

Although some reports have suggested the existence of “water-hammer” renal damage from high-grade reflux of sterile urine against the renal papillae (Hodson et al, 1975; Hagen and Klevmark, 1991), no such clinical entity has been predictably demonstrated. Because it is not reflux per se that is actually being managed, the hallmark of observational therapy in reflux disease can be more accurately termed “watchful waiting” while maintaining urinary sterility through the judicious use of single daily low-dose antimicrobial prophylaxis. Often, antibiotics are given as oral suspensions once per day and preferably at night. Nighttime dosing allows for antibiotic concentration in the bladder urine over the longest period of expected physiologic retention, when infection is most likely to develop. For children younger than 2 months of age, the most commonly used medications are trimethoprim and amoxicillin.

For further details, please see the Expert Consult website.

Breakthrough febrile UTIs or pyelonephritis while on antibiotic prophylaxis are generally considered an indication for termination of watchful waiting and correcting the reflux. However, individual documentation and verification of true breakthrough infection varies widely. Thus it is likely that instances of premature reflux correction (false positive) and failure to proceed with reflux correction (false negative) are to be expected. This possibility underscores the importance of proper antibiotic dosing, patient and parental

Guidelines: Treatments selected by 8 or 9 of 9 panel members, given the strongest recommendation language.

Preferred options: Treatments selected by 5 to 7 of 9 panel members.

Reasonable alternatives: Treatments selected by 3 to 4 of 9 panel members.

No consensus: Treatment selected by no more than 2 of 9 panel members.

*Recommendations were derived from a survey of preferred treatment options from 36 clinical categories of children with reflux. The recommendations are classified as follows:

†For patients with persistent uncomplicated reflux after extended treatment with continuous antibiotic therapy.

‡No consensus was reached regarding the role of continued antibiotic prophylaxis, cystography, or surgery.

\$See the text regarding the length of time that clinicians should wait before recommending surgery.

From American Urological Association. Report on the management of vesicoureteral reflux in children. Baltimore: American Urological Association, Pediatric Vesicoureteral Reflux Clinical Guidelines Panel; 1997.

Endoscopic management is discussed in greater detail later. In North America the relative ease and low morbidity of endoscopic correction has begun to transform the indications for unresolved reflux correction in females. Indeed, although open antireflux surgery is more technically demanding, as well as more taxing on the older female patient, endoscopic correction can be easily performed well into the teenage years and beyond. Between the age of 5 and mid-to-late teens, girls with asymptomatic reflux may be treated in the same fashion as boys and have their antibiotic prophylaxis withdrawn and follow-up imaging suspended for several years, in the absence of any febrile UTI. This also will afford the opportunity for a new cohort of older patients to provide longer term resolution rates on a systematic basis. Girls may then return for a final cystogram. If reflux is still present, endoscopic injection is performed followed by a postinjection cystogram. Formal prospective trials of this proposition will be required to validate the principle.

Moreover, studies of parental preference in reflux management are revealing that endoscopic treatment may sometimes be preferred over either antibiotic prophylaxis or open surgery depending on the perceived duration for reflux resolution (Ogan et al, 2001; Capozza et al, 2003). However, such studies must be interpreted with caution in that any therapy that combines low morbidity and technical ease can become a seductive choice, especially because endoscopic therapy was preferred despite an acknowledged lower success rate than that of open surgery and potential for more than one anesthetic. Alternatively, others may tolerate only definitive open surgical correction.

Notwithstanding the ethical considerations of proffering endoscopic treatment for reflux correction, endoscopic indications have a wider theoretic potential than open surgery. For example, even if the durability of endoscopic correction is not indefinite, recognizing that the prime age for postpyelonephritic scarring is younger than 5 years, one could conceive of temporary reflux correction by endoscopy for the early years, obviating the need for several years of prophylaxis in either males or females. Beyond 5 years, postinjection recurrence of asymptomatic reflux in males, were it to occur, would be of little clinical consequence. Males would require reevaluation only if pyelonephritis were to occur after the age of 5 years. In females, demonstration of durability of injection therapy extending from infancy to at least the end of the childbearing years would be required. One recent long-term study documents only a 5- to 7-year durability of 80% (Dodat et al, 2004); thus in one fifth of patients, reflux recurs. Moreover, these results represent the brand of injectable agent called Macroplastique (Uroplasty, Minnetonka, MN). Similar data are as yet unavailable for Deflux (Salix Pharmaceuticals, Raleigh, NC). Nevertheless, regardless of the substance injected and the uneven durability reported to date compared with open reflux correction, the endoscopic approach to reflux management has gained favor over the past several years in both Europe (Puri et al, 2003; Lendvay et al, 2006) and the United States.

Children younger than 2 months of age possess relative hepatic immaturity and are unable to clear sulfamethoxazole efficiently; the drug displaces fetal bilirubin and leads to jaundice. After 2 months of age, the antibiotic of choice becomes trimethoprim-sulfamethoxazole (TMP-SMX; Septra, Bactrim). Like virtually any drug, some mild side effects should be kept in mind and include gastrointestinal upset and allergy. Although transient leukopenia has been reported with TMP-SMX, it is rare, resolves with discontinuation of the drug, and is not believed to be significant enough to warrant regular monitoring of white blood cell counts in all children taking the drug. The other drug most commonly used is nitrofurantoin (Macrochantin). Nitrofurantoin may minimize the development of resistance to fecal organisms, the latter being the largest reservoir for urine infectivity. This drug is known to cause pulmonary fibrosis and, rarely, interstitial pneumonia. However, oral tolerance is less than with TMP-SMX because of taste and gastrointestinal symptoms are subjectively worse. A comprehensive literature review of the use of these drugs by Karpman and Kurzrock (2004) in children revealed a low incidence of significant hepatic (five patients) or pulmonary (nine patients) involvement, almost always associated with full-dose rather than once-daily low-dose therapy. Finally, a growing literature on the use of probiotics (live microorganisms such as strains of *Lactobacillus*, which may displace and suppress the growth of uropathogenic bacteria) is addressing UTI prophylaxis in children (Bruce and Reid, 2003; Reid and Devillard, 2004; Salvini et al, 2004). The mechanisms that underlie the demonstrated benefit of probiotic use are now emerging (Reid and Bruce, 2006; Storm et al, 2011). Further studies will be required to define the use of this attractive approach in the medical treatment of patients with reflux.

acceptance and compliance with the chosen therapy, and meticulous attention to proper collection and handling of urine culture specimens (see earlier discussion). Although the interaction between host defenses and bacterial virulence factors is what ideally dictates breakthrough infection, [Smellie \(1991\)](#) has provided useful interpretations surrounding practical causes of breakthrough infection: (1) If the organism is sensitive to the prescribed prophylactic antibiotic, the child or parent has likely not been compliant or the dose is too low. (2) If the organism is resistant to the prescribed antibiotic, either the residual bladder volume is too high too often or the dose is too high ([Smellie, 1991](#)). Indeed, many referrals for definitive reflux correction result from breakthrough UTI following full-dose antibiotic usage for extended periods.

Once the radiographic resolution of reflux has been documented, antibiotic prophylaxis is terminated, usually a few days after the cystogram. However, because reflux resolution will likely herald a tapering or discharge from regular urologic follow-up, this also is the precise time for reinforcing a lifelong adoption of good toileting and bladder behaviors.

In keeping with the notion of reflux resolution, recent studies have conducted multivariate analyses to construct predictive models for reflux resolution ([Knudson et al, 2007](#); [Estrada et al, 2009](#)). The assumption is that when reflux is less likely to resolve, the likelihood of ensuing complications is ever present and may sway management toward earlier or more proactive consideration for reflux correction in the individual patient. However, the converse also is true in that lifelong reflux, including persistent reflux per se may never be the cause of any morbidity. However, any standard instrument for the prediction of such morbidity is presently lacking. It appears that the factors associated with reflux resolution have become conflated with the more important factors that may be associated with its complications. Recent observations on the stratification of risk factors for reflux complications, in this case, breakthrough UTI, used a logistic regression model combining both reflux grade and clinical patient characteristics (gender, mode of reflux diagnosis, bowel/bladder dysfunction) to derive low-, intermediate-, and high-risk predictions for a breakthrough UTI within 2 years of follow-up ([Hidas et al, 2013](#)). This and subsequent tools that may follow show an advantage for counseling practitioners and families on more direct indications for both reflux intervention or relaxing follow-up, including a reconsideration of the ongoing need for prophylactic antibiotics. It is the consequences of reflux that pose the greatest threat; the ability to predict them rather than predict reflux persistence or resolution may be more clinically relevant.

Landmark Studies

The efficacy of medical management rests with a few key studies that came to define and establish watchful waiting as a cornerstone of therapy for reflux disease. Smellie and colleagues led a series of studies that repeatedly demonstrated the ability of low-dose prophylactic antibiotics to prevent infection and renal scarring while reflux resolved in a significant majority of children ([Edwards et al, 1977](#)). Since then two additional large-scale prospective studies validated this approach and helped to further define the natural history of VUR.

International Reflux Study in Children

The International Reflux Study in Children was a North American ([Weiss et al, 1992a](#)) and European ([Tamminen-Mobius et al, 1992](#)) cooperative study that randomized children younger than 9 years of age with high-grade reflux to watchful waiting with prophylaxis or corrective open surgery (see [Table 137-6](#)). Although surgery was complicated by temporary postoperative obstruction in some patients, it was more effective than prophylaxis in reducing, but not eliminating, the occurrence of pyelonephritis. Nevertheless, the incidence of UTI (38%) was the same with both modalities. Furthermore, the modalities were equally effective in reducing, but not eliminating, new scar formation. Only the European arm

stratified data for the effect of dysfunctional voiding behaviors (18%) ([van Gool et al, 1992](#)). When untreated, voiding dysfunction was associated with more UTIs, more persistent cases of reflux, and greater grade variation during follow-up.

Birmingham Reflux Study

Medical and surgical management was prospectively compared in a randomized cohort of 104 patients with high-grade reflux ([Birmingham Reflux Study Group, 1987](#)) over a 5-year period. Again, the incidence of new scars was the same using either treatment modality. Although more than half the patients continued to reflux at 5 years, all cases of new scarring occurred within the first 2 years, consistent with the “big bang” concept of postinfectious renal injury mentioned previously.

Additional Prospective Studies

Medical management alone was assessed in 59 patients (84 refluxing ureters, grades 1 to 3) by the Southwest Pediatric Nephrology Group ([Arant, 1992](#)). Resolution occurred in 67%, breakthrough infection in 33%, and new scarring in 10% of the low-grade and 28% of the patients with grade 3. [Scholtmeijer \(1993\)](#) demonstrated resolution in 57% of 47 cases of grade 3 to 4 reflux followed by watchful waiting and prophylaxis for 5 years. Interestingly, 15 cases underwent surgical correction after breakthrough infection and 6 of these subsequently developed new scars, whereas 2 of the patients managed medically developed new scars.

Randomized Intervention for the Management of Vesicoureteral Reflux Study

Despite the long-standing standard of care regarding medical management of VUR using prophylactic antibiotics, there exist mounting countervailing concerns over the long-term use of low-dose antimicrobials. These concerns are likely fueled at least in part by the documented abundant use of antibiotics both within the medical arena and in the food chain, as well as the rising incidence of antimicrobial resistance ([Cheng et al, 2008](#); [Alam et al, 2009](#)). Furthermore, newer prospective studies are beginning to question the ability of daily antibiotic prophylaxis to reliably reduce the incidence of UTI (see later). Reflux management is being further challenged by discordant and seemingly random recommendations variously for watchful waiting with or without antibiotic prophylaxis or first-line endoscopic, laparoscopic, or open correction of the reflux, depending on the individual consultant. The lack of appropriate (placebo) controls or observational arms in prior retrospective reflux studies has further called their conclusions into question. If daily low-dose antimicrobial prophylaxis is to maintain any position as a first-line treatment, its true efficacy will require greater scrutiny. One major study to address this question is termed the Randomized Intervention for the Management of Vesicoureteral Reflux (RIVUR study). RIVUR is a National Institutes of Health multicenter, double-blind, randomized, placebo-controlled trial designed to evaluate the effectiveness of antimicrobial prophylaxis in children found to have reflux after an initial UTI. Fifteen collaborating centers enrolled approximately 600 children with grade 1 to 4 reflux after an initial or second febrile or symptomatic UTI. Study participants were randomized to oral placebo versus oral TMP-SMX antibiotic prophylaxis. The primary outcome measure was the development of recurrent febrile or symptomatic UTI ([Chesney et al, 2008](#); [Greenfield et al, 2008](#); [Keren et al, 2008](#); [Mathews et al, 2009](#); [RIVUR Trial Investigators et al, 2014](#)). Results suggested that antibiotic prophylaxis reduced recurrent UTI risk by 50% (39 of 302 antibiotic vs. 72 of 305 prophylaxis subjects), particularly in subjects with febrile UTI or bowel/bladder dysfunction at baseline. However, renal scarring findings appeared unaffected by prophylaxis (11.9% vs. 10.2% in antibiotic vs. prophylaxis groups, respectively). Several limitations reiterate the significant challenges in conducting such studies. The compliance figures showed that

approximately 75% of antibiotic subjects took the drug only 75% of the time, almost a third discontinued the drug and were withdrawn from analysis, and 2% in each group reported adverse drug reaction. Using more stringent criteria for treatment failure (multiple UTI recurrences, \pm fever, \pm symptoms, etc.), twice as many placebo subjects suffered treatment failure (9.5% vs. 5% of antibiotic subjects). However, the converse is that 90% treatment success was achieved with placebo alone. Finally, 484 (83%) of baseline nuclear scans in both groups were obtained 1 to 4 months after the index infection event. However, the scan data cannot conclude whether positive baseline scan findings were a result of the index infection or were related to renal dysmorphism coincident with the genesis of reflux itself. Despite these limitations, this study nevertheless highlights the importance of balancing the consequences of UTI and its prevention in a reflux background (5% with prophylaxis vs. 9.5% with placebo) for both the patient and family as a whole (significant illness, hospitalization, loss of work) versus absence of any perceived benefit to the refluxing renal units per se. Greater attention to patient selection should help identify the specific subset of children who stand to benefit clinically from prophylaxis.

Antibiotic Controversies and Potential New Approaches

The principal rationale for antibiotic use in the management of reflux is in the prevention of urinary infection, principally febrile pyelonephritis, which may lead to permanent postinfection renal scarring. Driving this rationale in part is the belief that the first febrile UTI, in the presence of reflux, will create the greater proportion of clinically significant postinfection scarring, despite the fact that this concern is based on models of postinfection scarring in experimentally induced reflux in animals with a priori normal renal development (Torres et al, 1985). This belief, in turn, spawned the now routine and widespread sonographic follow-up of prenatal hydronephrosis for evidence of postnatal hydronephrosis, which, if present, then triggers the documentation of reflux by cystography to prevent the first febrile UTI by instituting immediate antibiotic prophylaxis if reflux is found.

However, several recent prospective studies have brought into question the ability of chronic low-dose antibiotic prophylaxis to prevent UTI in children. For example, in children with grade 2 to 4 reflux, after an initial UTI, randomization of 50 patients each to antibiotic prophylaxis versus no-treatment groups showed no difference in the rate of subsequent UTI or renal scarring (Pennesi et al, 2008). One multicenter trial of 225 children with reflux aged 1 to 3 years, randomizing subjects to antibiotic prophylaxis versus no treatment, found no statistical overall reduction in UTI incidence with prophylaxis, although subset analysis did suggest some benefit in boys with grade 3 reflux (Roussey-Kesler et al, 2008). As a corollary, patients with ongoing reflux in whom prophylactic antibiotics have been withdrawn have not suffered any increased incidence of UTI when compared with age-matched refluxing control patients who remain on prophylaxis (Leslie et al, 2009). Similarly, patients who have failed endoscopic reflux correction that remains uncorrected fail to show any increased incidence of UTI regardless of whether they remain on prophylaxis (Moore et al, 2009).

Such studies are plagued with a host of important shortcomings, including small patient numbers, high dropout rates, inaccurate urine collection methods (i.e., bags), no placebo controls, routine screening rather than evaluation in response to symptoms including screening bagged sample collections in uncircumcised infants, and lack of distinction between febrile and nonfebrile UTIs. Many of these shortcomings are being addressed in the large RIVUR study. Nevertheless, despite their limitations, these studies have succeeded in casting new doubt on the true and precise effectiveness and role of antibiotic prophylaxis in reflux management. However, in the recent Swedish Reflux Trial (Brandström et al, 2010c) girls 1 to 2 years old with grade 3 to 4 VUR prospectively randomized to antibiotic prophylaxis had a significantly lower incidence of new renal scars compared with those randomized to surveillance (no antibiotics) and endoscopic treatment. New scars were more prevalent after

febrile UTIs (11 of 49 [22%]). In contrast, only 4 of 152 (3%) of nonfebrile UTIs were associated with new renal damage ($P < .0001$). The rate of new renal damage was low in boys (observed in 2 of 75 males enrolled). These data support the use of antibiotic prophylaxis in girls younger than 2 years of age with grade 3 to 5 VUR.

Endoscopic correction of VUR did not reduce the incidence of new renal scars or febrile UTIs. However, the relatively low success rate of endoscopic treatment in this study (54% complete resolution with an additional 17% downgraded to grades 1 to 2) may have negated any potential benefit of endoscopic correction.

When added to the underlying concern for the long-term use of antibiotics in general, studies that bring into question the efficacy of antibiotic prophylaxis are giving rise to reflux management alternatives. Where low-dose antibiotic prophylaxis may be of questionable value, the effectiveness of appropriate full-dose antibiotic treatment of UTI by eliminating fever and symptoms of acute illness, as well as eradicating the infection, is not in question. Therefore one alternative is close observation for UTI symptoms without prophylaxis, coupled with precise treatment of culture-proved UTI. However, two recent pediatric nephrology studies of UTI (Doganis et al, 2007; Hewitt et al, 2008) suggest that early (within 24 hours) versus later (within 4 to 7 days) antibiotic treatment does not necessarily reduce the incidence of postpyelonephritic scarring if the kidneys become involved in the UTI, though early treatment may reduce initial renal involvement (Doganis et al, 2007). Moreover, in both studies, reflux was not found to be a significant variable affecting scarring incidence. In both studies, limitations such as precise knowledge of timing of UTI onset and the previously mentioned limitations of DMSA scanning in differentiating preexisting renal dysmorphism from true postinfection renal scarring (none of the foregoing study subjects had preinfection scans) remain.

With regard to endoscopic correction of reflux, the aforementioned chemoprophylaxis and invasive imaging concerns, the ease of endoscopic therapy, and parental preference for endoscopic correction despite knowledge of a lower success rate versus open surgery (Ogan et al, 2001) may be among the factors driving the resurgence and ever-increasing use of endoscopic correction of reflux. If this trend continues without rigorous prospective analysis, it could erode equipoise, to potentially position this technique as another first-line therapy after reflux diagnosis. Although studies of primary endoscopic therapy are emerging from South America and Europe (Nortes Cano et al, 2008), no North American studies endorsing this as a primary approach for low-grade reflux management are yet available. One uncontrolled retrospective study has suggested that endoscopic correction may reduce incidence of subsequent UTI, similar to the conclusion of the International Reflux Study, though endoscopic correction was not primary therapy (Wadie et al, 2007). More importantly, the durability of endoscopic reflux correction is in question, with the recent studies documenting 20% and 27% delayed recurrence of reflux after initial successful reflux correction (Sedberry-Ross et al, 2008; Holmdahl et al, 2010). Thus the indications for primary endoscopic correction of reflux will require carefully designed prospective randomized trials taking into account patient age and concomitant stage of renal development and renal susceptibility to scarring. In addition, other patient factors known to modify surgical outcomes such as preexistence or subsequent onset of elimination dysfunction must be considered. Finally, given the high incidence of incidental and clinically silent reflux in the normal population, as well as the high propensity for reflux to resolve over time, primary endoscopic correction of reflux without knowing which patients will benefit physiologically and clinically will likely result in both unnecessary correction of reflux destined to resolve naturally and/or correction of reflux with no clinical benefit.

Antibiotic prophylaxis is not a panacea—this approach is destined to fail without adequate teaching and periodic review of perineal hygiene techniques, timely bladder emptying habits, and anticonstipation measures. Similarly, family compliance with the antibiotic administration and follow-up visits for imaging may vary widely (Wan et al, 1996). Careful discussion of obligations and

expectations should take place to assess whether watchful waiting is appropriate in each case. Given the need for strict compliance with such an approach, alternative regimens such as alternate-day dosing of prophylactic antibiotics or early aggressive treatment of UTI with full-dose antibiotics with no prophylaxis otherwise, while conceptually attractive, will be at risk for decreasing compliance, especially when new opportunities for relaxing a daily routine and awareness are introduced into the management profile. If families or patients are willing but unable to maintain all the elements of a watchful waiting treatment regimen, then consideration for open or endoscopic correction of VUR may be relatively indicated.

KEY POINTS: NATURAL HISTORY AND MANAGEMENT

- Reflux has a natural tendency to resolve spontaneously.
- The likelihood of resolution is inversely proportional to grade.
- Maintaining urine sterility (through both prophylactic antibiotics and strict attention to bladder and bowel management) is the cornerstone of watchful waiting medical management.
- Continuous antibiotic prophylaxis results in a modest reduction in UTIs, but does not reduce renal scarring or chronic kidney disease.
- Prophylactic antibiotics are more likely to benefit patients with higher grade reflux, baseline bladder dysfunction, febrile UTI bowel and bladder dysfunction, or initial presentation with febrile UTI.

SURGICAL MANAGEMENT

Starting with Hutch's initial report on the successful correction of VUR in seven out of nine patients with paraplegia (Hutch, 1952), multiple surgical techniques have been described to effectively correct VUR. Currently, the principles from these techniques have been incorporated into a handful of procedures with excellent results. The choice of procedure is individualized according to surgeon experience and patient condition.

Surgical Principles of Reflux Correction

The principles of surgical correction of reflux include the following:

- Exclusion of causes of secondary VUR
- Adequate mobilization of the distal ureter without tension or damage to its delicate blood supply
- Creation of a submucosal tunnel that is generous in caliber and satisfies the 5:1 ratio of length to width recommended by Paquin (1959)
- Attention to the entry point of the ureter into the bladder (hiatus), the direction of the submucosal tunnel, and the ureteromucosal anastomosis to prevent stenosis, angulation, or twisting of the ureter
- Attention to the muscular backing of the ureter to achieve an effective antireflux mechanism
- Gentle handling of the bladder to reduce postoperative hematuria and bladder spasms

The surgical procedures can be classified on the basis of the approach to the ureter as *intravesical*, *extravesical*, or *combined*. Furthermore, they can be classified on the basis of the position of the submucosal tunnel in relation to the original hiatus into *suprahiatal* or *infrahiatal*.

The following components apply to all of the various surgical techniques. The surgeon is free to select the appropriate components tailored to the patient's anatomy to achieve a successful ureteral reimplant. Prophylactic antibiotics may be administered with induction of anesthesia. The patients are generally admitted the

morning of the surgery unless there are specific reasons requiring preoperative admission. Enemas are reserved for only select cases because all issues related to dysfunctional elimination should be addressed when the diagnosis of VUR is made.

Cystoscopy

Historically, many centers performed cystoscopy after the diagnosis of VUR with the premise that it offers a predictive assessment of the likelihood of spontaneous resolution of VUR. Parameters such as shape (except for the golf hole orifice associated with high-grade reflux) and location of the ureteric orifice and the submucosal tunnel length were subsequently found not to have a predictive value (Duckett and Bellinger, 1982). Therefore cystoscopy in the course of conservative management of VUR is indicated only to confirm or manage abnormalities found on other imaging modalities (Ferrer et al, 1998).

Some surgeons choose to perform cystoscopy at the time of ureteral reimplantation surgery after induction of anesthesia. This is helpful in identifying subtle anomalies not detected on preoperative imaging, particularly if an extravesical technique is employed and the bladder is not opened. Preoperative cystoscopy may uncover inflammatory changes, trabeculation, duplication anomalies, or anatomic anomalies at the UVJ such as small ureteroceles or diverticula.

The bladder should be examined as it is distending, because a paraureteral diverticulum may not be apparent until the bladder is moderately to fully distended. Some authors suggest the use of hydrodistention of the ureteric orifice (Kirsch et al, 2004), particularly of the contralateral ureter, as a predictor of which ureters will develop contralateral reflux after surgery. PIC cystography (Rubenstein et al, 2003) also has been recommended for the detection of occult reflux in children who have had febrile UTI and a negative VCUG. In both of these techniques the tip of the cystoscope is positioned at the ureteric orifice and the irrigating fluid flow (with or without radiographic contrast) is directed at the ureter. The elevation of the anterior wall of the ureter, allowing visualization of the ureteral lumen, and/or the retrograde flow of contrast detected by fluoroscopy is considered to be indicative of an incompetent UVJ that might reflux during a UTI or after contralateral surgery but remains to be validated.

At the completion of cystoscopy the bladder is left half full if an intravesical technique is contemplated. If an extravesical technique will be used, a Foley catheter connected to a three-way adapter can be inserted to allow bladder distention to facilitate the dissection of the detrusor flaps.

Positioning

The child is positioned supine. To facilitate exposure of the bladder, especially in older children and adolescents, a rolled towel may be placed at the level of the upper sacrum or a slight break in the table is used to raise the lower pelvis and hips. All pressure points are appropriately padded, and a wide surgical preparation is performed. The hips are abducted slightly to allow access to the urethra in girls if required; in boys the penis is prepared and draped in the field.

Incision

A Pfannenstiel skin incision, along a skin crease, is made approximately 2 cm above the symphysis pubis to the lateral edges of the rectus muscles. If the child is exceptionally overweight, the classic Pfannenstiel can be extended. The anterior rectus fascia is opened in a transverse fashion and elevated superiorly to just below the umbilicus and inferiorly to the symphysis pubis. The pyramidalis muscles attach between the pubic bone and the anterior rectus sheath. Thus they should not be separated from the rectus sheath. The bellies of the recti are then separated in the midline exposing the bladder. Alternatively, after the skin and Scarpa fascia are incised, the skin can be mobilized off the anterior rectus sheath and the linea alba can be opened in the midline vertically.

INTRAVESICAL PROCEDURES

Approaching the Ureters

The peritoneum is gently swept off the dome of the bladder. This is easier with a moderately full bladder. The bladder is opened in the midline down to approximately 2 cm proximal to the bladder neck. Figure-of-eight stay sutures, using 3-0 Prolene, are placed at the junction of the lateral edges with the bladder dome and at the inferior apex of the incision to prevent extension of the incision into the bladder neck. A Denis Brown retractor provides excellent exposure. Saline-soaked sponges are folded and gently packed into the dome of the bladder and also placed along the lateral edges of the bladder incision. Three blades of the retractor are used to retract the lateral walls of the bladder and the dome. The retractor blades should be placed with the utmost care, and minimal touching, suctioning, or rubbing of the bladder mucosa are recommended to prevent edema or inflammation of the mucosa, which can lead to bleeding and difficult mucosal dissection and may aggravate the bladder spasms in the postoperative period.

Intravesical Mobilization of the Ureter

The ureter(s) is cannulated with a 3- or 5-Fr Silastic feeding tube that is sutured to the bladder mucosa at the inferior edge of the ureteric orifice with 5-0 Prolene. This serves to maintain orientation of the ureter during all phases of the procedure and is used to handle the ureter and apply gentle traction. Before ureteral mobilization, some surgeons inject epinephrine 1:200,000 submucosally to reduce the bleeding. Using needle-point cautery, a circumscribing incision is made in the bladder mucosa approximately 1 to 2 mm away from the ureteric orifice. With gentle traction on the feeding tube, the ureter can be mobilized into the bladder. Mobilization of the ureter is best started at the 6 o'clock position by spreading the blades of the tenotomy scissors gently in a posterior direction initially. Once the correct plane is entered, the dissection is carried out circumferentially. The adventitia of the ureter must not be violated to prevent ischemic injury to the ureter. The ureter is freed from its attachments to the bladder using a fine right-angle clamp and electrocautery. This is aided by gentle traction on the feeding tube. Dissection of the ureter is continued until it can reach the contralateral bladder wall without tension. At that point the surgeon is ready to develop the submucosal tunnel using the same ureteral hiatus or a suprahiatal technique, depending on experience and preference.

SUPRAHIATAL TUNNELS

Politano-Leadbetter Technique

The principle behind this technique, which was originally described by Politano and Leadbetter (1958), is to bring the ureter in through a new hiatus superior to the original insertion. A submucosal tunnel is created in the direction of the trigone, medial to the original orifice. The advantage of this technique is that a long tunnel can be created, which is valuable in the higher grades of reflux. This anti-reflux mechanism can be further supported by a psoas hitch.

Technique

After completion of the ureteral mobilization intravesically, the location of new hiatus is selected in a **straight line superior to the original orifice** (Fig. 137-17). With the bladder open and the lateral walls retracted, the inexperienced surgeon might be inclined to position the new hiatus too laterally on the posterior wall. Once the bladder is closed and full, the ureter enters on the anterolateral wall and then hooks back posteriorly toward the trigone, creating the classic "hooking," which is an important cause for postoperative ureteral obstruction. In the original description of the Politano-Leadbetter technique, the new hiatus was created blindly by passing a right-angle clamp from the original hiatus behind the bladder to

puncture through the posterior wall of the bladder at the new hiatal opening. This blind maneuver must be discouraged because it is the cause of significant complications that may be associated with this procedure, such as routing the ureter intraperitoneally, injury to bowel, vas deferens, vagina, or other nearby structures. The current approach is to retract the superior lip of the original hiatus with a stay suture or a vein retractor and clear the back wall of the bladder bluntly under direct vision. A right-angle clamp is then used to create a new hiatus through which the ureter enters the bladder. The submucosal tunnel is created in the direction of the trigone, medial to the original orifice. The length of the tunnel depends on the diameter of the ureter. A 5:1 ratio (length to width) as suggested by Paquin (1959) is a helpful guide. It is important to lift the mucosa off the detrusor at the point of entry of the ureter into the bladder so that the mucosa can be closed properly over the new hiatus. The tunnel should be capacious enough to prevent constriction of the ureter. The ureter is pulled through the tunnel, and the feeding tube is removed.

Ureteral Anastomosis

The ureter is spatulated ventrally (at the 6 o'clock position), and the edges are freshened if necessary. Three interrupted sutures of 5-0 polyglactin placed relatively close to each other anchor the ureter to the trigone by suturing it to the bladder muscle and mucosa. The anchoring sutures should be placed carefully because the apex of the spatulation is the narrowest point of the ureter. The remainder of the ureteral anastomosis is carried out with interrupted 5-0 polyglactin sutures at the 3-, 9-, and 12-o'clock positions. The 12-o'clock suture also may be used to evert the anterior wall of the ureter, thus creating a small cuff. Although a 5-Fr feeding tube passed up the ureter confirms patency and absence of kinks, the most reassuring sign that the ureteral reimplant is not obstructed is to see the jet of urine emerging from the orifice. It is thus important to communicate to the anesthesiologist the importance of adequate fluid administration throughout the case. The mucosa overlying the new hiatus is closed with a running 5-0 polyglactin suture. The bladder is closed in two layers using a 3-0 polyglactin suture. A Foley catheter is used to drain the bladder for 48 hours; drains and stents are only employed for the more complex cases.

Paquin Technique

Please see the Expert Consult website for details.

INFRAHIATAL TUNNELS

Glenn-Anderson Technique

In 1967 Glenn and Anderson described their technique of ureteral reimplantation (Fig. 137-18). By using the same hiatus and advancing the ureter distally toward the bladder neck, the potential complications associated with the Politano-Leadbetter technique, specifically kinking of the ureter, are avoided. The ureter is mobilized as described earlier. A submucosal tunnel is created toward the bladder neck using tenotomy scissors. The distance from the hiatus to the bladder neck limits the length of the tunnel. Glenn and Anderson (1978) later described a modification that allows creation of a longer tunnel by incising the detrusor proximally at the original hiatus. The detrusor edges are then reapproximated distal to the ureter. With advancement of the ureter toward the bladder neck, the distal anastomosis of the ureter could be challenging with this technique. As with the other procedures, the results with this technique are excellent, with a 98% success rate (Gonzales et al, 1972).

Cohen Cross-Trigonal Technique

Cohen's technique (1975) overcomes the limitation of the tunnel length in the Glenn-Anderson technique by directing the tunnel across the trigone toward the contralateral bladder wall (Figs. 137-19

Paquin described this combined extravesical/intravesical technique in 1959 (Paquin, 1959). The new ureteral hiatus is created from outside the bladder, thus avoiding the difficulties associated with this maneuver in the Politano-Leadbetter technique. As with most of the other open techniques, a success rate greater than 95% for primary VUR is achieved with this method (Woodard and Keats, 1973).

The ureter in the Paquin technique can be approached extravesically (see Extravesical Procedures) before opening the bladder. A right-angle clamp is applied at the UVJ, the ureter is divided, and a 3-0 polyglactin suture is used to suture ligate the original hiatus. The bladder is then opened in the midline, and a new hiatus is created, located cephalad to the prior position. The peritoneum is carefully cleared off the back wall of the bladder at the site of the new hiatus. A right-angle clamp is passed from inside the bladder under direct vision, and one end of a 5-mm Penrose drain is pulled into the bladder. A mosquito snap is applied to the Penrose drain, which acts as a holder and facilitates the creation of the submucosal tunnel. The mucosa is dissected off the detrusor circumferentially at the new hiatus. The length of the submucosal tunnel is governed by the diameter of the ureter, and a 5:1 ratio is usually achievable. In more complex cases a psoas hitch may be required to achieve a longer tunnel length. The tunnel is developed by carefully lifting the mucosa off the detrusor using tenotomy scissors. Countertraction on the mucosa is helpful, especially in cases that must be redone and when the bladder wall is trabeculated. Once the tunnel is developed the remainder of the reimplants is similar to the Politano-Leadbetter procedure.

The modified Paquin technique is particularly suited for dilated ureters and complex (El-Sherbiny et al, 2002) and failed reimplants (Mesrobian et al, 1985) because of the versatility offered by the combined extravesical/intravesical approach to the ureter and the ability to achieve longer submucosal tunnel lengths.

Figure 137-17. Politano-Leadbetter technique. A, Typical approach to the bladder for reimplantation. A transverse, lower abdominal incision (*dashed line*) is made along a skin crease one or two fingerbreadths above the symphysis pubis. B, Fine sutures are placed above and below the ureteric orifice for handling. A feeding tube in the ureter aids in the initial dissection. C, A needle-tip cautery outlines a circumferential incision around the orifice. D, Tenotomy scissors initially establish the plane of dissection inferiorly, where ureteral damage can be avoided. The plane is then carried around the ureter.

Continued

Figure 137-17, cont'd E, With the aid of a lighted suction tip and two Senn retractors, a fine gauze dissector is used to sweep the peritoneum from the posterior bladder wall. F, After sweeping the peritoneum away, a blunt right-angle clamp indents the bladder from behind at a new hiatus approximately 2.5 cm superior and somewhat medial to the original hiatus. G, The clamp is incised on from within and generously spread to make certain that the new hiatus is wide enough. H, A second right-angle clamp follows the first from within the bladder to the original hiatus.

Figure 137-17, cont'd I, The right-angle clamp grasps the stay suture, and the ureter is pulled through the new hiatus. J, The inferior lip of muscle at the new hiatus is divided for a few millimeters to eliminate any ureteral angulation at its entrance to the submucosal tunnel that is created with scissors. K, The ureter is brought through the new tunnel to the original hiatus. L, The ureter is anastomosed to the original hiatus in the classic Politano-Leadbetter technique. Proximal mucosa can be closed over the ureter to give the tunnel additional length. M, Ureteral advancement is also helpful, especially if the original hiatus is laterally positioned. A second submucosal tunnel can be created toward the bladder neck to place the new orifice in a more inferior position and gain additional length for the reimplant. (A to D and F to M, from Retik AB, Colodny AH, Bauer SB. *Pediatric urology*. In: Paulson DF, editor. *Genitourinary surgery*, vol. 2. New York: Churchill Livingstone; 1984. p. 757-63; E, from Keating MA, Retik AB. *Management of failures of ureteroneocystostomy*. In: McDougal WS, editor. *Difficult problems in urologic surgery*. Chicago: Year Book; 1989. p. 121.)

Figure 137-18. Glenn-Anderson technique. The ureter is mobilized and advanced beneath a new submucosal tunnel. (From Glenn JF, Anderson EE. Distal tunnel ureteral reimplantation. *J Urol* 1967;97:623.)

Figure 137-19. Cohen cross-trigonal technique, unilateral reimplantation. After the ureter is freed (A), a submucosal tunnel is made, with the new mucosal hiatus just above the contralateral ureteral orifice (B). (From Retik AB, Colodny AH, Bauer SB. *Pediatric urology*. In: Paulson DF, editor. *Genitourinary surgery*, vol. 2. New York: Churchill Livingstone; 1984. p. 764.)

Figure 137-20. Cohen cross-trigonal technique, bilateral reimplant. A, The more superior ureter is tunneled transversely, with its new orifice just above the contralateral orifice. B, The other ureter is tunneled inferiorly, with its new orifice located at the inferior-most portion of the contralateral hiatus. (From Retik AB, Colodny AH, Bauer SB. *Pediatric urology*. In: Paulson DF, editor. *Genitourinary surgery*, vol. 2. New York: Churchill Livingstone; 1984, p. 765.)

and 137-20). The difficulty with the distal anastomosis in the Glenn-Anderson technique is also eliminated.

Cohen's technique is particularly suited for small or thick-walled bladders (PUV or neuropathic) because the ureteral advancement across the back wall of the bladder rarely results in kinks or obstruction. The cross-trigonal reimplant is also the procedure of choice in conjunction with bladder neck reconstructive procedures because the superior displacement of the ureters provides room for adequate elongation of the bladder neck.

As a result of its simplicity and reliable results (up to 99% [Glassberg et al, 1985; Kennelly et al, 1995; McCool and Joseph, 1995; El-Ghoneimi et al, 1999]), Cohen's procedure has become the most commonly employed intravesical reimplant.

Critics of this technique cite the difficulty of retrograde catheterization of the superolaterally positioned ureteral orifice for radiographic studies, insertion of stents, and management of ureterolithiasis as significant disadvantages. Suggested approaches to overcome this include suprapubic cystostomy by trocar (Lamesch, 1981) or 14-gauge, 5-cm intravenous cannula in conjunction with cystoscopy to direct the ureteral catheter into the ureter or by using a curved-tip vascular access catheter and an angle-tipped glide wire with a torque device (Wallis et al, 2003) or the use of a flexible ureteroscope.

Method

1. The technical methods of the Cohen and Glenn-Anderson procedures are similar in many aspects.
2. The ureter is approached and mobilized using the standard intravesical approach.

3. A hiatal groove may be created on the medial side of the ureter to reduce the angulation of the ureter as it crosses transversely, especially when the bladder wall is thickened. If the hiatus is excessively patulous, it can be reapproximated with one or more interrupted 3-0 polyglactin sutures to avoid diverticulum formation (Ahmed and Tan, 1982). The hiatus should easily accommodate the tips of a large right-angle clamp alongside the ureter to avoid obstruction of the ureter.
4. The submucosal tunnel is developed using the tenotomy scissors as previously described. When only one ureter is reimplanted, the tunnel is directed superior to the contralateral ureteric orifice. If both ureters are reimplanted, the tunnel for the more laterally displaced ureter is directed superior to the contralateral orifice. The second tunnel is directed toward the inferior edge of the orifice of the laterally displaced ureter. A common submucosal tunnel has been used successfully for bilateral reimplants (Androulakakis et al, 2003).
5. The ureter is spatulated and anastomosed to the bladder mucosa as described in the Politano-Leadbetter technique. The mucosa over the old hiatus is closed with 5-0 polyglactin sutures.
6. Alternatively, the mucosal cuff of the ureteric orifice may be preserved and anastomosed to the bladder mucosa without spatulation.
7. The ureter is catheterized with a 5-Fr feeding tube to ensure patency, although the continuous efflux of urine from the orifice provides the best assurance of patency.
8. Closure of the bladder and drainage is completed as described previously.

EXTRAVESICAL PROCEDURES

Lich and colleagues (1961) in the United States and Gregoir (1964) in Europe independently described the extravesical approach to ureteral reimplantation (Fig. 137-21). The technique became more popular after the modifications described by Daines and Hodgson (1971), and Zaontz and colleagues (1987) popularized anchoring the ureter with advancement sutures. These modifications allow for a combined advancement of the ureter and lengthening the tunnel proximally. In addition, anchoring sutures fix the ureter distally and thus maintain stability of the tunnel. The advantage of the extravesical technique is that the bladder is not opened; thus postoperative hematuria and bladder spasms are minimized. The technique is simple to learn and is readily taught.

The main concern with this technique has been the development of transient voiding inefficiency that is seen in up to 20% (Fung et al, 1995; Lapointe et al, 1998; Lipski et al, 1998; Barrieras et al, 1999; Marotte and Smith, 2001) of children who undergo bilateral extravesical reimplants. The mechanism is thought to be due to disruption of the nerves to the bladder bilaterally, possibly resulting from excessive use of cautery during the detrusorotomy. The population most at risk appears to be boys younger than 3 years of age with bilateral high-grade reflux (Barrieras et al, 1999).

Leissner and colleagues (2001) used human cadavers to study the topography of the pelvic plexus in an effort to understand the mechanism of injury to the plexus resulting from extravesical reimplant surgery. They demonstrated that the main portion of the pelvic plexus is located approximately 1.5 to 2 cm dorsal and medial to the UVJ in adult cadavers. Smaller branches travel along the medial aspect of the ureter, outside the thin layer of tissue (the mesoureter) that surrounds the ureter. On the basis of their anatomic description, injury to the branches of the pelvic plexus is avoided if dissection of the distal ureter is carried out between the mesoureter and ureteral adventitia. Yucel and Baskin (2003) further refined the description of the neuroanatomy of the distal ureter and UVJ using immunohistochemical analysis and 3D imaging techniques in normal human fetuses (21 to 40 weeks of gestation). They confirmed the localization of the nerves along the medial aspect of the ureter just outside the Waldeyer sheath. At the UVJ the nerves surround the ureter in a network-like fashion; distally, once the ureter enters the bladder, the nerves localize on the detrusor muscle

distal and lateral to the ureter. From these two studies it is suggested that the incidence of voiding inefficiency observed after bilateral extravesical reimplants depends on the surgical technique. The injury is limited to the smaller nerve branches rather than the actual pelvic plexus, which is located medially and posteriorly. The neural damage may be due to transection of the nerves, electrocautery, or neuropraxia caused by surgical trauma. Injury to the nerves may be prevented by limiting the dissection to the correct plane, just outside the ureteral adventitia, reducing the use and power of electrocautery, restricting the incision of the detrusor distal to the UVJ, and gentle handling of the tissues (David et al, 2004).

Patients who develop urinary retention, requiring insertion of a Foley catheter or intermittent catheterization, are able to void within 1 to 2 weeks (Minevich et al, 1998a; Barrieras et al, 1999), indicating the reversibility of the neurologic lesion.

Approaching the Ureters

A Pfannenstiel incision is used as described earlier. It is best to have the bladder somewhat distended to this point to facilitate dissection of the peritoneum of the lateral bladder wall. The obliterated umbilical artery is identified. The ureter crosses medial to the point of origin of the obliterated umbilical artery from the internal iliac artery. This is an excellent anatomic reference point for identification of the distal ureter. Dividing the obliterated umbilical artery facilitates dissection and mobilization of the ureter. Some authors were concerned that the injury to the bladder innervation occurs when the obliterated umbilical artery is divided. However, Lipski and colleagues (1998) demonstrated that there was no difference between two groups of patients regardless of whether the obliterated umbilical artery was divided. The peritoneum is meticulously reflected off the anterior surface of the ureter. To avoid injury to any of the branches of the pelvic plexus, it is recommended that the surgeon stay right on the ureter during its dissection while being careful not to injure blood vessels running in the ureteral adventitia. A vessel loop is passed around the ureter and used as a handle. Dissection and mobilization of the ureter is carried distally to the point where it tunnels under the detrusor muscle.

Creation of the Extravesical Tunnel

With the bladder in its normal anatomic position, the course of the ureter along the posterior wall of the bladder is identified and marked for a distance of 5 cm. The bladder is reflected medially; a Denis Brown retractor is quite helpful for this procedure. The outlined course of the ureter is inspected. The peritoneal reflection may need to be gently lifted off the wall of the bladder. With the bladder retracted, the tunnel direction will appear to be pointing toward the anterior abdominal wall. It is important to have the bladder full and somewhat tense but not overstretched. The detrusor is incised using low-current electrical cautery (15 W) to create the new submucosal tunnel. After that, tenotomy scissors are used to divide the detrusor fibers along the same line of the initial incision down to the bladder mucosa. Care should be taken to incise the detrusor fibers along one line, without wandering sideways, to facilitate lifting the detrusor off the mucosa with minimal disruption to the detrusor muscle and its innervation. Blood vessels are easily seen as one incises the detrusor fibers, and these are cauterized selectively with bipolar cautery. It is critical that all detrusor muscle bundles are divided before elevation of the detrusor flaps. When the last detrusor bundles have been divided, a **uniform** mucosal dome bulges out. This provides the surgeon with an excellent point of reference that the tunnel has been established in the correct plane.

The detrusor is dissected off the mucosa on either side of the incision, for a width slightly larger than the circumference of the ureter. This dissection is best carried out from proximal to distal, leaving the dissection around the ureter as the final step of the tunnel creation.

There is a definite **avascular** plane between the muscle and the mucosa. The most efficient method to realize this dissection is to

Figure 137-21. Modified Lich-Gregoir/detrusorrhaphy technique. A, The ureter is identified and gently grasped after ligation of the obliterated hypogastric artery. B, The ureter is circumferentially mobilized at its intersection with the bladder by incising the detrusor at the level of the ureteral hiatus. C, The serosal and muscular layers of the bladder (4 to 5 cm) are opened along a straight course cephalad and lateral from the ureterovesical junction to create the trough for reimplantation. A tacking suture aids in orientation. D, The bladder mucosa is elevated off muscle wall, and vest-type sutures are placed from the detrusor at the distal limit of dissection to the proximal ureteral adventitia and back again through the same tissue planes. Tying of the vest sutures advances and anchors the ureter onto the trigone. E, Reapproximation of the detrusor creates a long submucosal tunnel and completes the repair. (From Peters C, Retik AB. Ureteral reimplantation including megaureter repair. In: Marshall FF, editor. Textbook of operative urology. Philadelphia: Saunders; 1996. p. 868–70.)

have the assistant grasp the detrusor bundles closest to the mucosa with two forceps, elevating the muscle off the mucosa. The surgeon gently depresses the mucosal bulge with one hand and uses the tenotomy scissors to sharply separate the muscle bundles off the mucosa, on either side, along the length of the tunnel. Injury to the mucosa during dissection of the tunnel is quite avoidable unless the bladder is thick walled and trabeculated. Inadvertent injury to the mucosa could be closed with a 6-0 polyglactin figure-of-eight suture. It is not necessary to create a wide tunnel unless the ureter is very dilated.

Particular attention is necessary when dissecting around the ureter. The detrusor fibers attached to the ureter are carefully divided, staying close to the ureter to avoid injury to any of the terminal nerve branches entering the bladder. The dissection is carried out along the lateral and medial attachments of the ureter but is not extended distally.

The original modification described by [Zaontz and colleagues \(1987\)](#) for the extravesical procedure included incision of the detrusor distal to the ureteric orifice for 5 to 10 mm with advancement of the ureter using two vest sutures. [Leissner and colleagues \(2001\)](#) demonstrated that this particular aspect of the procedure may be responsible for injury to the bladder innervation at the trigonal area and may be the lead cause of urinary retention in bilateral extravesical reimplants. Therefore, to avoid damage to the nerves, this maneuver should be avoided unless there is a paraureteral diverticulum that requires repair simultaneously ([Jayanthi et al, 1995](#)). In those cases, dissection of the detrusor distal to the ureter should be carried out in a limited fashion.

Once creation of the submucosal tunnel is complete, the bladder is decompressed before reapproximation of the detrusor. The ureter is positioned in the new tunnel, and the detrusor reapproximated using interrupted 3-0 polyglactin sutures. To achieve alignment of the tunnel, it is best to place the most proximal suture first at the new ureteral hiatus and to leave it untied and tagged on a mosquito snap. Tension applied to this suture straightens and elevates the detrusor flaps, allowing the surgeon to reapproximate the detrusor without risk for injury to the ureter or the mucosa. The suturing commences at the most distal portion. The adventitia of the ureter may be incorporated in one or two of these sutures to stabilize the tunnel and prevent a diverticulum from forming at the most distal or proximal portion of it. At the completion of the suture line, the caliber of the hiatus should be tested with a right-angle clamp to ensure absence of any constriction or compression of the ureter.

The bladder is refilled and the retractor is removed. The course of the ureter is reinspected to ensure absence of any kinks in the retroperitoneum or any bulging of the mucosa at either end of the tunnel.

A Foley catheter is left for 24 to 48 hours; some authors recommended not leaving a catheter at all ([Marotte and Smith, 2001](#)). If an epidural caudal catheter is inserted for postoperative analgesia, it should be discontinued 6 to 12 hours before removal of the Foley catheter.

If the child is observed to void without problems, he or she is discharged, to return for a follow-up sonogram and a VCUG usually 3 months postoperatively.

POSTOPERATIVE EVALUATION

In expert hands the success rate for ureteroneocystostomy in patients with low-grade primary VUR approaches 100%. As a result of these outstanding outcomes, several centers have evaluated the need for postoperative invasive imaging. Most agree that a sonogram is necessary at 6 to 12 weeks postoperatively. In a large study by [Barrieras and colleagues \(2000\)](#), 723 renal units were evaluated. At 1 year postoperatively there was a significant difference between children who had undergone surgery for low-grade primary VUR (99% resolution) versus those with high-grade reflux (94%). Thus, in patients who initially had low-grade primary reflux, in whom the preoperative and postoperative ultrasound examinations were normal and do not have voiding dysfunction or recurrent UTIs ([Lavine et al,](#)

[2001](#)), the success rate with uncomplicated ureteroneocystostomy approaches 100% ([Bisignani and Decter, 1997](#); [Bomalaski et al, 1997b](#); [El-Ghoneimi et al, 1999](#); [Barrieras et al, 2000](#); [Grossklauss et al, 2001](#)). On the basis of these reports, it has been suggested that the postoperative VCUG can be avoided in this group of patients. This recommendation should be individualized on the basis of the family situation and the expertise of the center performing the surgery. Some families have followed reflux for several years and are anxious to know with certainty that the reflux has resolved. In other families, the children are quite reluctant to undergo another VCUG, and in this situation it may be reasonable not to perform a postoperative study unless the child has a dysfunctional bladder or develops postoperative hydronephrosis or UTIs. However, the lower success rate for high-grade reflux would still support complete postoperative studies in most cases.

After ureteroneocystostomy, the presence of minimal ureteral dilation and low-grade hydronephrosis on early postoperative ultrasonography is not unusual ([Bomalaski et al, 1997b](#); [Barrieras et al, 2000](#)). Indeed, this common finding should argue against performing such studies too early after surgery. On the other hand, persistence of this dilation beyond 3 months or its progression should be further investigated ([Aboutaleb et al, 2003](#)). Additionally, the development of new renal scars on late follow-up ultrasonography, a discrepancy in renal growth, or recurrent UTIs may warrant complete radiologic re-evaluation of the patient.

As discussed previously, children with renal scarring should have their blood pressure measured at every visit with their family physician.

COMPLICATIONS OF URETERAL REIMPLANTATION

Early Complications

Persistent Reflux

Early reflux after ureteroneocystostomy usually is not a significant clinical problem and commonly resolves by 1 year on repeat cystography. In the report by [Barrieras and colleagues \(2000\)](#), 49 of 723 renal units had reflux at 3 months, 11 of which were contralateral. At 12 months' follow-up, reflux resolved spontaneously in 20 of the 38 ipsilateral and in 8 of the 11 contralateral ureters. Persistent reflux at 1 year was more common in patients who had high-grade reflux preoperatively. In their study 30% of patients undergoing surgery had high-grade reflux. Two thirds of those with persistent reflux at 1 year (12 of 18) were from that group. Thus the majority of low-grade postoperative reflux detected in the initial VCUG at the 3-month follow-up point disappeared spontaneously, likely because of the resolution of the bladder inflammation and improvement in bladder dysfunction that may be present in the early postoperative period.

Contralateral Reflux

The issue of contralateral reflux has been the subject of several reports in the literature over the past 15 years, most of which are retrospective ([Hubert et al, 2014](#)). [Minevich and colleagues \(1998b\)](#) and [Burno and colleagues \(1998\)](#) noted a low incidence of contralateral reflux after unilateral extravesical detrusorrhaphy in 5.6% and 11.6% of their patients, respectively. [Diamond and colleagues \(1996b\)](#), in a multicenter trial of 141 patients, reported an 18% incidence of contralateral VUR. These patients were analyzed according to grade of initial reflux, presence of a Hutch diverticulum or duplex system, and the surgical technique employed to correct the reflux. No difference was noted among the various surgical techniques, but there was a significant trend toward development of contralateral reflux with the higher grades of ipsilateral corrected reflux and correction of reflux in duplex systems. They concluded that the distortion of the contralateral hemitrigone was not a responsible factor for contralateral reflux but rather the severity (grade 5) of reflux, and the presence of a duplex system put patients at risk for development of contralateral reflux postoperatively. Conversely,

Kumar and Puri (1997) reported on 495 children with unilateral reflux who had undergone subureteral Teflon injections. New contralateral reflux was diagnosed in only 37 children (7%). They were unable to find any correlation between the grade of preoperative ipsilateral reflux and postoperative contralateral reflux and suggested that low incidence of new contralateral VUR may be due to a relative noninterference with the contralateral trigone afforded by endoscopic compared with open reflux correction. They refuted the existence of the pop-off mechanism accounting for new contralateral reflux in their series because the risk for new contralateral reflux did not correlate with the preoperative reflux grade (grades 4 and 5). Sparr and colleagues (1998) reviewed a series of 143 patients on conservative management and initially diagnosed with unilateral reflux but subsequently developed metachronous contralateral reflux. Contralateral reflux appeared in 33%, suggesting a different cause for the appearance of contralateral reflux unrelated to surgical correction. They speculated that the contralateral reflux was in fact synchronous (i.e., bilateral) but missed on initial cystogram or that the natural history of unilateral or bilateral reflux may involve intermittent appearance and disappearance of VUR on one side.

Prophylactic bilateral reimplantation for unilateral reflux, to avoid contralateral reflux, is not warranted on the basis of the high spontaneous resolution rates (Burno et al, 1998). Recommendations for management of contralateral reflux range from observation in the majority of cases to intervention for control of clinical pyelonephritis episodes. In asymptomatic children, younger than 4 to 5 years of age, prophylactic antibiotics are warranted for postoperative contralateral reflux, particularly if one is to be consistent with the medical therapy for the previous ipsilateral reflux. If the child remains asymptomatic and infection free, repeat VCUGs may not be necessary because contralateral reflux resolves spontaneously in the majority of children. In girls around the age of puberty, controversy persists as to whether a VCUG and correction of reflux at that point become necessary. In a recent report by Hubert and colleagues (2014) from Boston, new contralateral reflux was observed in 10% of the children (18% grade 1, 70% grade 2, and 12% grade 3). Younger age (<6 years) and low observed bladder capacity (<50% of predicted capacity) were significant predictors of contralateral reflux on multivariable analysis. Follow-up cystography documented resolution of contralateral reflux in almost 80% at a median of 21.5 months, confirming the benign nature of this vexing problem.

Obstruction

It is not unusual to detect a mild-to-moderate degree of hydronephrosis in the early postoperative period by ultrasonography (see earlier discussion). This should resolve spontaneously with time. Acute postoperative obstruction may be related to technical issues such as twisting or kinking of the ureter in its new tunnel, intramural blood clots, or extramural compression by submucosal hematoma or edema at the site of anastomosis. Progressive, significant obstructions usually become apparent in the first 2 weeks after surgery. The children typically present with symptoms of acute ureteral obstruction, including acute abdominal pain, nausea, and vomiting. Although infection is less common, if it occurs it is quite significant in the obstructed system. The diagnosis is readily made on ultrasonography, and the severe hydroureteronephrosis is confirmed by delayed function and excretion on renal scintigraphy. In the more significant cases, drainage of the system either by retrograde insertion of a double-J stent or a percutaneous nephrostomy tube may be necessary. The nephrostomy tube should be internalized as early as possible to avoid a dry reimplant. Many of these cases resolve without requiring additional surgery.

LONG-TERM COMPLICATIONS

Obstruction

Progressive dilation of the ureter and kidney after reimplantation surgery can be due to several factors and can be classified on the basis of the location of the obstructive lesion.

Suprahiatal

Twists of the ureter and ischemia result from poor handling of the ureter and are the most common causes of suprahiatal obstruction.

Hiatus

At the point of entry into the new hiatus, angulation of the ureter occurs, most commonly as a result of a hiatus that is positioned too lateral or anterior such that when the bladder fills, the ureter becomes carried laterally and anteriorly, resulting in the "high reimplant" phenomenon. These ureters drain better when the bladder is empty. This situation may resolve spontaneously but on occasion requires stenting or repeat surgery.

Tunnel

A submucosal tunnel that is not adequately developed can lead to compression of the ureter causing obstruction within the tunnel. The submucosal tunnel is obviously more difficult to develop in an abnormal bladder such as the valve or neuropathic bladder. Developing a smooth, capacious, submucosal tunnel can be quite challenging because of the irregularities created by the muscular hypertrophy, trabeculation, and cellulite formation. Ischemia to the ureter and the submucosal tunnel is another important factor that results from improper handling of the ureter, leading to its devascularization. Significant obstruction in the submucosal tunnel can be overcome by balloon dilation and stenting for a time. If conservative measures are unsuccessful, reimplantation is required.

Orifice

The anastomosis of the ureter to the bladder and the new hiatal position is an important technical aspect of the reimplant procedure. The most vulnerable point for obstruction is the apex of the ureteral spatulation. The apical sutures must be placed with the utmost care to ensure an adequate orifice caliber. Stenosis also can occur as a result of ischemic changes. Isolated obstruction of the orifice can be managed by dilation and stenting. If the submucosal tunnel is of adequate length, endoscopic unroofing of the distal few millimeters, including the orifice, may relieve the obstruction while maintaining the antireflux mechanism.

Recurrent or Persistent Reflux

Failure of antireflux procedures in primary low-grade reflux is extremely rare. Most failures are due to either high-grade reflux or an inadequate ratio of tunnel length to ureteral diameter. Development of a short tunnel and failure to taper the excessively wide ureter are obvious important factors. Another significant cause of persistent or recurrent reflux is failure to recognize secondary reflux, especially associated with neurogenic bladders and PUV bladders. **Reflux in these situations is secondary to the poor storage or emptying characteristics of the bladder. These issues need to be addressed and optimized before reimplant surgery is attempted.** In most situations, improving bladder storage and/or emptying with a combination of an anticholinergic agent and intermittent self-catheterization results in spontaneous resolution of secondary reflux (Agarwal et al, 1997). Proceeding with reimplantation surgery in the presence of an abnormal bladder results only in worsening of the ureteral dilation and deposition of scar tissue in the pelvis, which would render future attempts at correcting the reflux even more difficult.

REDO REIMPLANTATION

Redo reimplantation is technically more challenging and requires careful attention to detail and meticulous surgical technique. Dissection of the ureter and extensive mobilization are required to achieve an adequate submucosal tunnel. Careful dissection of the ureter is best accomplished by a combination of extravesical and

Figure 137-22. A psoas hitch can be used to effectively bridge significant ureteral defects. Its combination with transureteroureterostomy is ideal when both ureters are addressed in a reoperative setting. (From Keating MA, Retik AB. Management of failures of ureteroneocystostomy. In: McDougal WS, editor. Difficult problems in urologic surgery. Chicago: Year Book; 1989. p. 140.)

intravesical mobilization as needed. The ureter should be carefully evaluated and ischemic segments excised. Free bleeding from the divided distal end should be observed in addition to peristaltic activity, ensuring normal musculature and blood supply. It is preferable to create a new hiatus and submucosal tunnel. If the ureter is shorter, a psoas hitch (Fig. 137-22) can be used to facilitate the creation of the antireflux mechanism. The psoas hitch should be carried out with nonabsorbable suture before creation of the submucosal tunnel. The bladder is fixed to the psoas muscle sheath on either side of the iliac vessels, providing a stable posterior bladder wall. In children, the bladder can be mobilized sufficiently to bring it up almost to the bifurcation of the common iliac vessels. This may provide adequate bridging for a distal ureteral defect. A psoas hitch can be achieved only on one side. Attempting a psoas hitch on both sides will not provide adequate length on either side and thus should be avoided. If both ureters are shortened, consider a psoas hitch on one side to achieve a satisfactory antireflux mechanism with a transureteroureterostomy for the other ureter.

Other techniques to consider for the short ureter include the Boari flap, in which a flap extending from the dome to the anterior wall of the bladder based on the posterior wall can be rotated proximally. The flap should be wide enough to allow creation of a submucosal tunnel and tubularization of this flap. In the short ureter a nipple valve can be created in association with a short submucosal tunnel. The nipple valve is particularly useful in dilated ureters and is fashioned by spatulating the ureter and folding it back onto itself.

In situations in which the ureter is significantly foreshortened, it can be replaced using a reconfigured segment of bowel as described by Pope and Koch (1996). The colon or ileum is reconfigured similar to the Monti procedure. This technique offers important advantages over the classic tapered ileal ureter, allowing a long tube to be created from a short segment of colon without tapering, thus eliminating the metabolic consequences; additionally, the mesentery is in the center of the tube, which facilitates creation of the submucosal tunnel.

ENDOSCOPIC TREATMENT OF VESICoureTERAL REFLUX

(See Fig. 137-23.)

Matouschek (1981) first described the injection of polytetrafluoroethylene (PTFE) paste at the ureteral orifice to correct VUR. O'Donnell and Puri (1986) popularized the technique when they

Figure 137-23. Principle of endoscopic treatment of reflux. A bulking agent is injected beneath the ureteral orifice with a needle. The buttress that is provided helps coapt the distal end of the ureter.

published their initial report on the successful endoscopic correction of primary VUR in 103 ureters with a success rate of 75% after one injection. They coined the term *STING* (Subureteric Teflon Injection). This procedure became popular in many countries but never achieved widespread use in the United States because of lack of U.S. Food and Drug Administration (FDA) approval over concerns regarding the potential migration of PTFE particles (Malizia et al, 1984a, 1984b; Aaronson et al, 1993). The ability to correct reflux in a large proportion of patients (the more recent studies report success rates approaching 90% after one injection of Deflux in low-grade primary reflux [Kirsch et al, 2004]) on an outpatient basis using a simple procedure with minimal morbidity prompted the search for safer materials. One caveat when evaluating the reported results of endoscopic correction is to interpret with caution reports in which the authors regard downgrading of reflux to grade 1 or 2 (Sweden) as a successful outcome. Because this would not be acceptable to most surgeons performing open surgery, the definition of success should be applied uniformly.

Because of the minimal morbidity of the procedure, the benefit of endoscopic injection in newly diagnosed patients has been evaluated using computer modeling with a view to reduce the morbidity and cost of repeated VCUGs and long-term antibiotics (Kobelt et al, 2003). Rigorous comparisons of various treatment approaches need to be undertaken, and until the outcomes of such studies are available, the indications for correction of reflux should remain unchanged, whether reflux is corrected by open surgery, endoscopy, or laparoscopy.

Two key challenges with endoscopic treatment of reflux are reproducibility and durability of the results. Long-term follow-up will determine whether endoscopic therapy, with the currently available materials, will stand the test of time or if open surgery with its 95% to 99% success rate will remain the most cost-effective way of permanently correcting reflux.

Technique of Endoscopic Injection

The classic STING technique was described by O'Donnell and Puri (1984) (Fig. 137-24). Prophylactic antibiotic is usually administered with induction of anesthesia. A cystoscopy should be carried out before opening the materials in case the procedure is canceled because of inflammatory changes in the bladder. If a rigid needle is used, an offset lens injection scope should be used. If a flexible needle is used, a standard 0- or 30-degree lens cystoscope can be used. The size of the needle varies depending on the viscosity of the material and ranges from 3.7 to 5 Fr. The viscosity of the material also determines whether injecting the material can be carried out using a regular syringe or requires a ratcheted metal syringe holder. A 3-Fr ureteral catheter may be introduced to lift up the anterior

Figure 137-24. The classic subureteral Teflon injection (STING) technique. **A**, Appearance of the orifice before hydrodistention (**B**). **C**, The entry point of the needle is 2 mm distal to the 6-o'clock position. **D**, Appearance of the mound after completion of the injection.

wall of the ureter and identify the axis of the tunnel. The needle is inserted with the bevel facing up at the 6 o'clock position. The original description by O'Donnell and Puri suggested entering the mucosa 2 to 3 mm distal to the UVJ and advancing the needle in the submucosal plane for a distance of 4 to 5 mm. For high-grade reflux and ureters without submucosal tunnel, the Dublin group suggested inserting the needle directly inside the ureter to increase the length of the intravesical ureter (Chertin et al, 2002, 2003). Kirsch and colleagues (2004) popularized this approach (submucosal implantation within the intramural ureter) and reported improved results with all grades of reflux compared with the classic technique (92% vs. 79% of ureters). They further modified the technique with addition of a second injection inside the orifice and named it the double hydrodistention implantation technique (HIT), resulting in further improvement (93%) in intermediate and long-term results (Kalisvaart et al, 2012).

The accuracy of the needle entry point and needle placement is an important component for success of the procedure (Fig. 137-24). An improper puncture may not result in the desired mound formation and thus may not provide adequate support for the UVJ. If the needle requires repositioning, the implanted material may leak out of the first puncture site, resulting in failure of the procedure.

Injection should be carried out slowly. If the needle is positioned in the submucosal plane, the mound becomes apparent with the initial injection of 0.1 to 0.2 mL. This is a key point in the procedure; unsatisfactory mound formation and location after this initial injection is an indicator that the tip of the needle is not in the proper position. Repositioning of the needle by withdrawing it slowly and then advancing it while injecting, in addition to rotating the bevel gently (depending on the lateral location of the mound), should help achieve the desired effect. Once a volcano appearance with the ureteral meatus on top of the mound is achieved, additional volume is injected until the ureteric orifice becomes crescent or slit shaped. The shape of the achieved mound was found to be a significant predictor of a successful outcome. Achieving a volcano-shaped mound was associated with an 87% success rate, whereas other morphologies were associated with only a 53% successful rate (Lavelle et al, 2005). For most materials, the needle should be kept in place for 1 minute at the end of the injection to reduce extrusion of the material at the injection site. With Deflux this step is not essential. The bladder is emptied, and the mound is inspected with an empty and a full bladder to ensure that adequate support of the

ureter is persistent. Rarely, bleeding occurs at the puncture site. This is best dealt with by emptying the bladder and applying gentle pressure with the tip of the scope until the bleeding stops. Cauterizing the area is not advisable because it results in sloughing of the mucosa and extrusion of the injected material. At the end of the procedure, lidocaine gel may be instilled in the urethra; catheter drainage is not necessary. In general the child spends a brief amount of time in the recovery room, followed by discharge. All activities can be resumed immediately.

There is a significant learning curve with endoscopic correction of VUR (Kirsch et al, 2003). In a study by Herz and colleagues (2001) the importance of the learning curve was highlighted. In the first 6 months of their study the success rate was 46% in 18 children with 28 refluxing ureters. In the remaining 18 months of that study, the overall correction rate was 93% in 56 children with 84 refluxing ureters after a single endoscopic injection. Although the technique is quite simple once learned, there are some technical nuances and details that require specific attention.

Follow-Up

The child is maintained on antibiotics for 3 months when a follow-up sonogram and VCUG are obtained. If reflux is persistent, a repeat injection can be considered 6 months after the initial injection. If there is still no resolution, open surgery is recommended.

Most reports to date have not indicated any additional difficulty with open surgery after endoscopic correction using Deflux (Herz et al, 2001; Lackgren et al, 2001), but some have experienced difficulty with other substances. At open surgery the injected material is either not seen at all or is found well encapsulated but in an incorrect plane or location inside or outside the bladder. The material is easily removed en bloc, and the open reimplant procedure carried out without difficulty.

Materials Used for Endoscopic Correction of Reflux

For an injectable biomaterial to be ideal, it must be nontoxic and stable without migration to vital organs. It should cause minimal local inflammation, while at the same time be well encapsulated by normal fibrous tissue and fibrocytes. The material should be easy to inject through a long needle that passes easily through most standard endoscopic instruments. It must be viscous enough to prevent leakage from the puncture site and maintain its injected volume and the mound shape after the normal process of exchange and excretion of any carrier molecules.

Several agents have been used for endoscopic correction of VUR. These materials can be classified as **particulate or degradable and autologous or nonautologous** (Box 137-1).

The concern with the particulate agents is migration and with degradable agents is durability. Distant migration can occur by two mechanisms. The first is expansion of the injected bolus, which

may lead to disruption of the small vessels in the area of the distal ureter and trigone, resulting in the material gaining intravascular access. Particles smaller than 50 μm may bypass the pulmonary vascular bed and thus access the systemic circulation and reach other organs in the body. The second migration mechanism is by phagocytosis of the injected particles by tissue macrophages or blood-borne monocytes. The particle size determines whether phagocytosis can occur, because it is generally agreed that phagocytosis requires a particle less than 80 μm in diameter.

NONAUTOLOGOUS MATERIALS

Polytetrafluoroethylene Paste (Teflon Paste)

PTFE has been in use as a component of many biomaterials and injectable agents for many years. It has been used for the manufacturing of vascular grafts, cardiac valves/implants, surgical sutures, cosmetic surgery, and patches for hernia repairs (Monaghan and Meban, 1991; Godin et al, 1995; Sayers et al, 1998; Briguori et al, 2001). Teflon paste also was used as an injectable agent for embolization of vessels (Weingarten and Kauffman, 1977), for injection of vocal chords (Kasperbauer, 1995), and as a bulking agent for urinary incontinence (Politano, 1992).

Matouschek (1981) first reported on the use of Teflon paste as a bulking agent for correction of reflux. O'Donnell and Puri (1984) and Chertin and Puri (2002) popularized this technique and reported on its use in hundreds of patients with long-term follow-up (Puri, 1995; Chertin and Puri, 2002). A large European multicenter survey reported on 6216 ureters and 4166 children with 10 years of follow-up and demonstrated a cure rate of 86% after one to four injections (Puri et al, 1995). The longest follow-up is available from Dublin; 247 patients treated with Teflon paste with 11 to 17 years of follow-up demonstrated a sustained success rate of 95% with a 5% recurrence rate (Chertin and Puri, 2002).

Teflon paste is relatively inexpensive; it is viscous and requires a ratcheted syringe for injection. Despite its widespread use in Europe, Teflon paste never gained FDA approval in the United States because of concerns regarding distant migration of the PTFE particles. Malizia demonstrated in experimental studies that the particles can migrate to regional lymph nodes and to distant organs, including the lung and the brain (Malizia et al, 1984a, 1984b). Malizia's findings were substantiated by several clinical reports confirming particle migration (Claes et al, 1989; Aaronson et al, 1993; Dewan and Fraundorfer, 1996; Steyaert et al, 2000). Particle migration is thought to be related to the small size of the Teflon paste particles, which range from 4 to 100 μm , with 90% of the particles less than 40 μm .

With the availability of other, presumably, safer injectable agents, PTFE has fallen totally out of favor and been all but abandoned.

Cross-Linked Bovine Collagen

Please see the Expert Consult website for details.

Polydimethylsiloxane

Please see the Expert Consult website for details.

Dextranomer and Hyaluronic Copolymer

Dextranomer/hyaluronic copolymer (DX/HA) (Deflux) is formed of cross-linked dextranomer microspheres (80 to 250 μm in diameter) suspended in a carrier gel of stabilized sodium hyaluronate. DX/HA is biodegradable, the carrier gel is reabsorbed, and the dextranomer microspheres capsulated by fibroblast migration and collagen ingrowth. DX/HA loses approximately 23% of its volume beyond 3 months of follow-up (Stenberg and Lackgren, 1995).

Deflux was first introduced by the Swedish group of Stenberg and Lackgren (1995) and received FDA approval in 2001. Since then several clinical reports from Europe and the United States have documented success rates ranging from 68% to 89% (Lackgren

et al, 2001; Puri et al, 2003; Kirsch et al, 2004; Lavelle et al, 2005). The introduction of the double HIT by the Atlanta group has resulted in higher reflux resolution rates in 90% of 336 children (Kaye, 2012).

In a long-term follow-up study by Lackgren and colleagues (2001), 68% of 221 children injected using the classic STING technique and followed for a mean of 5 years maintained grade 1 VUR or less at the last VUCG. No significant long-term adverse effects were noted. Salvage ureteral reimplantation after failed endoscopic correction with DX/HA can be accomplished, usually without difficulty. The implant bolus is frequently observed in the periureteral space outside the bladder and is well encapsulated, with mild inflammatory changes (Sparks, 2011).

The appeal of DX/HA is that it is a natural product that is easily administered without a ratcheted syringe through a smaller gauge needle. It is currently the preferred agent for endoscopic correction in most centers; however, the durability of correction of VUR with DX/HA remains to be proved.

Calcium Hydroxyapatite

Calcium hydroxyl apatite (CaHA) (Coaptite; Bioform Medical, San Mateo, CA) is synthetic bone material. The particles have a uniform spherical shape and range in size from 75 to 125 μm . The material injects easily through a 21-gauge needle without the need for a ratcheted syringe. Mevorach and colleagues (2002) presented the initial results in a clinical trial including 98 patients and 155 ureters with grade 2 to 4 reflux. Reflux resolved in 67% of the patients and 75% of the ureters. In a recent consecutive case series from Stanford University the success rate per ureter was lower for CaHA (52%) than for DX/HA (78%) (Ngo et al, 2013).

AUTOLOGOUS MATERIALS

Fat, collagen, muscle, and chondrocytes have been evaluated as bulking agents. The key advantage of these agents is that they are not foreign materials, but the obvious disadvantage is the observed volume loss (up to 100% in the case of fat [Matthews et al, 1994]) and that they need to be harvested and expanded (in the case of chondrocytes and muscle) before injection. Autologous materials behave as a free graft at the injection site, so reabsorption of the material is worrisome and may be responsible for the inconsistent results.

Other Injectable Substances

Please see the Expert Consult website for details.

Recurrence of Vesicoureteral Reflux after Endoscopic Correction

The true incidence of recurrent VUR after successful endoscopic correction with any specific material is difficult to determine because a repeat VCUG is not obtained beyond the initial negative study except in the context of a research protocol.

Only a handful of series have reported long-term follow-up with repeat VCUG beyond the initial negative study. Chertin and colleagues (2002) reported a 5% recurrence rate using Teflon paste with follow-up up to 17 years. In the Swedish Reflux Trial, 20% of previously successfully treated children had a recurrence after 2 years of follow-up (Holmdahl et al, 2010).

The higher recurrence rate with Deflux, an absorbable agent, is not unexpected. However, in the absence of UTIs, the significance of confirming the long-term absence of VUR is less important. Furthermore, even if absorbable bulking materials were to lose volume or reabsorb completely over time, VUR resolution may be maintained by growth of the child and maturation of the UVJ. The injectable agent may just have bought time for this process to conclude. The implication of recurrent reflux in young adulthood

Apart from concerns regarding allergy to bovine collagen in 3% of the population, this material is otherwise safe and causes minimal local inflammatory changes (Leonard et al, 1990). It is easily injectable through a 25-gauge needle with standard endoscopic equipment. The downside to cross-linked collagen is the fact that the results are not durable because of the variable degree of ingrowth of native fibroblasts and replacement of the injectable collagen with native collagen (Leonard et al, 1990, 1991; Frey et al, 1992). Despite the odd report of sustained effect (Reunanen, 1995), the inconsistency, and questionable durability of cross-linked collagen (Haferkamp et al, 2000a, 2000b), most centers have abandoned its use for correction of reflux.

Polydimethylsiloxane (PDS) (Macroplastique) is a solid silicone elastomer that has been used as a soft tissue bulking agent. The injectable material is composed of soft, flexible, highly textured implants of heat-vulcanized PDS suspended in a bioextractable carrier gel. The carrier gel is a water-soluble low-molecular-weight polyvinylpyrrolidone hydrogel (Povidone). The carrier gel is absorbed and replaced with host fibroblasts that subsequently deposit collagen, encapsulating the implant. The implant retains its size and shape. To minimize the risk for migration, PDS is engineered to create an elastomer, instead of the less cross-linked silicone gels or non-cross-linked silicone oils. Although 76% of particles are greater than 100 μm in diameter, 7% are less than 50 μm in diameter. The smaller particles (Henley et al, 1995) and possible intramuscular injection of the agent are responsible for migration of particles to the lungs, kidneys, brain, and lymph nodes demonstrated in animal models. Unlike Teflon paste, Macroplastique does not cause an intense local inflammatory response. In patients requiring open surgery after failed injection with Macroplastique, the injectable bolus was found encapsulated and easily removed without adherence to the ureter or bladder (Herz et al, 2001). Histologic examination of the bladder muscle biopsies and pelvic lymph nodes at the time of open surgery revealed a mild inflammatory reaction with no evidence of PDS particle migration in either the wall of the bladder or the draining lymph nodes.

The efficacy of PDS as a bulking agent for correction of reflux is well documented. Dodat and colleagues (2004) reported on the long-term outcomes of Macroplastique injections for correction of VUR. Results in 590 refluxing ureters in 389 patients who were injected with a minimum follow-up of 5 years revealed a sustained success rate of 79.4%. Herz and colleagues (2001) demonstrated a reflux resolution rate of 81% after a single injection and 90% after a second injection with a 12-month follow-up. Similarly, van Capelle and colleagues (2004) reported an 82.3% success rate in 311 ureters in 195 children over a 10-year period from two European centers.

The main advantage of PDS is that it is a permanent material that remains well encapsulated, causing minimal local inflammatory changes. A recent report, however, draws attention to the development of Macroplastique bolus calcification occurring in 3 of 232 children injected between 1998 and 2004. Patients presented with worsening hydronephrosis, hematuria, and irritative lower urinary tract symptoms 5 to 9 years after injection. At time of surgery the calcified material was extracted after unroofing the overlying eroded mucosa (Lorenzo et al, 2010). This report underscores the importance of long-term monitoring after the injection of foreign bodies in growing children. Despite its demonstrated long-term track record, PDS has yet to achieve FDA approval for correction of VUR in the United States, possibly because of concerns regarding migration, particularly particles that are smaller than 80 μm , and the negative connotations associated with silicone implants.

Chondrocytes

Atala and colleagues (1993, 1994) described the harvesting and expansion of chondrocytes in vitro and successful correction of VUR in animal models. Subsequently, human trials using chondrocytes harvested from the posterior auricular cartilage were conducted (Diamond and Caldamone, 1999; Caldamone and Diamond, 2001). The chondrocytes were grown in culture for 6 weeks, quantitated, concentrated, and then suspended in a mixture of sodium alginate and calcium sulfate solution for injection. At 3-month follow-up, reflux was corrected in 55% (27 of 47) of the ureters. This improved to 86% after one or two repeat injections. At 1-year follow-up, reflux correction was maintained in 70% (32 of 46) of the ureters and 60% (19 of 29) of the patients. At subsequent endoscopy, failures were attributable to volume loss and shifting of the subureteral mounds.

Polyacrylate Polyalcohol Copolymer (Vantris)

Polyacrylate polyalcohol copolymer (PPC) (Vantris; Promedon, Córdoba, Argentina) belongs to the family of acrylics, which are nonbiodegradable agents of synthetic origin. PPC particles average 320 μm and are highly deformable by compression and thus may be injected using a 23-gauge needle. After implantation of particles, a fibrotic capsule of up to 70 μm forms around the implant providing stability and presumed long-term permanence. Recently published results demonstrate a promising reflux correction rate of 92.7% per ureter in 109 children and 165 ureters after a single injection (Chertin et al, 2013). To date PPC has yet to receive FDA approval.

for these patients is inadequately defined at present. More recent evidence suggests that children undergoing endoscopic correction with a preinjection history of multiple febrile UTIs, BBD, and renal scarring are at a higher risk for recurrent infections and late recurrence of VUR despite initial negative VCUG (Sedberry-Ross et al, 2008).

Endoscopic correction of VUR is a reasonable alternative for children being considered for surgical correction; however, families should be informed of the varied success rates across centers and that outcomes may not be durable.

Laparoscopy as Applied to Correction of Reflux

The laparoscopic approach to ureteral reimplantation should theoretically provide the success rate and durability of open surgery while avoiding its morbidity. Three procedures have been attempted laparoscopically: the extravesical reimplant, the Gil-Vernet procedure, and the Cohen cross-trigonal reimplant.

In addition to the long operative times and steep learning curve, the initial experience with laparoscopic reimplantation identified significant technical challenges in the creation of the submucosal tunnel while maintaining an intact bladder urothelium and with the suturing aspects of the procedures. The enhanced dexterity and outstanding visualization offered by the robot facilitates the laparoscopic reimplantation; however, the current port size required is still not ideal for smaller children. The continued refinement of open reimplantation surgery, more recently dispensing with the use of both postoperative bladder catheters and the need for overnight hospital stays, will place even greater onus on the proponents of the laparoscopic approach to better define the ideal candidates for minimally invasive technique.

LAPAROSCOPIC SURGICAL PROCEDURES

Gil-Vernet Procedure

In this procedure the trigonal mucosa is incised vertically and the two ureters are approximated into the midline with a single submucosal suture. This procedure has been accomplished laparoscopically transvesically with limited success. Okamura and colleagues (1999) and Cartwright and colleagues (1996) reported success rates of 59% and 62.5%, respectively. The recurrence of reflux is thought to be due to splitting of the trigone and lateral displacement of the ureters. This procedure is the least successful amongst the three described laparoscopic techniques and is all but abandoned.

Laparoscopic Extravesical Reimplant

In 1994 Ehrlich and associates first described the extravesical Lich-Gregoir technique through a transperitoneal approach (Ehrlich et al, 1994). This is the most commonly used procedure for laparoscopic correction of reflux. The technique has a steep learning curve; initial experiences described challenges with exposure of the ureter, trauma to the ureter, difficulty developing the extravesical tunnel without injuries to the urothelium, and long operative times.

Separation of the urothelium from the detrusor is difficult laparoscopically because the adequately distended bladder protrudes into the limited pelvic working space and hinders the laparoscopic dissection. Additionally, the ability to adequately retract the incised detrusor edges to create a wider trough is limited because of the exposure and the angles at which the instruments enter the abdomen.

Several modifications of the technique have been described by Lakshmanan and Fung (2000), leading to a more effective procedure with shorter operative time and results that approximate those of open surgery.

Trocar Placement

A 5-mm, 0-degree laparoscope is inserted through the umbilicus. Three additional working ports are inserted in the lower abdomen

along the lines of a Pfannenstiel incision in the middle and on either end.

Ureteral Dissection

The ureter is best identified at the pelvic brim and followed distally. The overlying peritoneum is incised transversely. Ureteral catheters placed cystoscopically may aid in identification of the ureter in the older patient. Once the ureter is identified, it can be grasped with Babcock forceps and freed from the surrounding tissues. In males the incision of the peritoneum should be carried out caudal to the vas deferens so that the vas can be reflected with the peritoneum in a cephalad direction. A vessel loop or a Diamond-Flex retractor can be passed around the ureter and used as a holder.

Creation of the Tunnel

It is important to mark the direction of the tunnel with electrocautery while the bladder is semidistended in its normal position. A 4-0 Prolene traction suture is applied at the proximal end of the detrusor tunnel. This suture is passed through the abdominal wall on a straight needle and used to hitch the bladder, and then the needle is passed out again, providing external control to achieve the desired tension and elevation of the detrusor. The incision of the detrusor is carried out starting from proximal to distal. The serosa is scored with cautery, but most of the dissection should be carried out using scissors to prevent injury to the bladder innervation, as described in the discussion of open extravesical reimplant earlier in the chapter. Elevation of the detrusor flaps is more difficult in the laparoscopic procedure, and therefore a trough as wide as that developed with open surgery may not be achievable. The incision is continued distally around the ureter, leaving the distal attachments intact. The mucosal bulge is also not as obvious as in open surgery because the bladder is not as distended and is also compressed by the peritoneal insufflation.

Closure of the Myotomy (Detrusorrhaphy)

The ureter is placed in the new tunnel, and a 3-0 polyglactin suture is placed at the most proximal end to stabilize the ureter and facilitate reclosure of the detrusor with interrupted sutures starting at the ureteral orifice distally. Anchoring sutures are not required because the distal attachments of the ureter are left intact.

After completion of the detrusorrhaphy, the bladder retraction suture is released and the bladder is filled. The ureter is observed in its new tunnel to confirm the absence of angulation or kinking. A catheter may be left in the bladder for 12 to 24 hours postoperatively.

The largest published series is that of Lakshmanan and Fung (2000) in which 71 ureters were reimplanted laparoscopically. Early on in that series, three ureteral injuries required open reimplantation in two and stenting in one to drain a urinoma. The remaining patients are free of reflux and obstruction.

Robotic Approach

Despite the initial successful reporting of the laparoscopic approach, its widespread use was limited by the significant technical demands and long operative times. In 2004, Peters was first to describe the initial experience with robotic-assisted laparoscopic ureteral reimplantation (RALUR) in the pediatric population (Peters, 2004). The major advantages of the robot over pure laparoscopic techniques are the 10× visual magnification and 3D visualization, in addition to reducing the technical challenges of fine suturing in the small spaces. The surgeon also benefits from the improved ergonomics of the robot console where the surgeon sits during the procedure; this is particularly helpful for longer or bilateral procedures (Lendvay, 2008).

In the most recent series, the reported results of robotic extravesical reimplantation closely approximate the success rates of the open procedure. Casale and colleagues (2008) reported a 97.6%

success rate in 41 patients using a transperitoneal robotic-assisted approach. An update of their experience was recently published (Kasturi et al, 2012) documenting a 99.3% reflux resolution rate in 150 patients with grade 3 or greater bilateral VUR. The one failure was a patient with bilateral grade 5 VUR that was downgraded to unilateral grade 2 VUR that was subsequently corrected with a sub-ureteral injection therapy after an episode of pyelonephritis. More significantly, in this group of 150 toilet-trained children, no patient experienced de novo voiding dysfunction. In a comparative study, RALUR was reported to demonstrate a reduction in length of stay and use of postoperative opioids relative to open surgery (Smith et al, 2011).

The current advantages of RALUR over the laparoscopic approach are anticipated to be enhanced by further equipment refinement and reduction in port and instrument size. However, the cost of the console, instruments, and disposables associated with RALUR are significantly higher and may remain a critical limitation in many countries.

Endoscopic Cross-Trigonal Reimplant

To avoid transgressing the peritoneum and the challenges associated with the small pelvis in the child, other groups have developed a transvesical approach, similar to the Cohen cross-trigonal reimplant, using carbon dioxide insufflation of the bladder (pneumovesicum).

Yeung and colleagues (2005) initially described the procedure using standard laparoscopic instruments. Peters and Woo (2005) followed with a report describing a robotically assisted technique to facilitate the creation of the submucosal tunnel and the ureteral anastomosis.

Port Placement

The patient is positioned supine with the legs separated to allow access to the urethra for cystoscopy and bladder catheterization intraoperatively. Cystoscopy is carried out, and the bladder is distended with saline. A traction suture is passed percutaneously at the level of the bladder dome under cystoscopic vision to anchor the bladder wall to the abdomen and prevent it from pulling away when the camera port incision is made at the dome. Yeung and colleagues (2005) described the placement of a U-hitch stitch, tightened over a short piece of rubber tubing outside the abdomen, to prevent port dislodgement and gas leakage into the extravescical space. After that, a 5-mm port is inserted under cystoscopic vision. The cystoscope is removed, and a urethral catheter is inserted. Carbon dioxide insufflation to 10 mm Hg pressure is started, and a 5-mm, 30-degree lens is inserted. Two additional 3-mm working ports are inserted on either side of the bladder under direct vision.

Dissection of the Ureter

A 5-cm segment of a 5-Fr feeding tube is inserted in the ureter and secured with a 4-0 Prolene suture. The catheter facilitates handling and dissection of the ureter as described in the open Cohen procedure. The ureteral mobilization begins with the usual circumscissoring incision using the hook electrocautery. The 3-mm endoscopic scissors are used to develop the plane of dissection starting on the distal aspect of the ureter. The dissection is carried out circumferentially for a distance of 2 to 3 cm. The muscular defect in the ureteral hiatus is repaired before creation of the tunnel to reduce gas leak, using 4-0 absorbable sutures.

Creation of the Submucosal Tunnel

An incision is made using the hook cautery at the site of the new ureteric orifice across the back wall of the bladder. The submucosal tunnel is started from the old hiatus toward the new hiatus using fine endoscissors. A fine grasper is then inserted through the new hiatus, and the feeding tube is used to pull the ureter through the tunnel.

Ureteral Neocystostomy

The ureter is spatulated at the 6-o'clock position and anastomosed at the new location using 6-0 interrupted sutures. Peters and Woo (2005) described using the robot to facilitate the delicate suturing laparoscopically and improve the efficiency of the procedure. The port sites in the bladder are closed, and an indwelling urethral catheter is maintained for 24 hours. Reflux resolution was demonstrated in 15 of 16 patients in series reported by Yeung and colleagues (2005) and in 5 of 6 patients in the series reported by Peters and Woo (2005). Providing a detailed description of the nuances of the vesicoscopic technique, Jayanthi and Patel (2008) reported a 94% success rate in a larger series of 103 patients, 10 of whom failed endoscopic injection. Three patients were converted to open surgery early in their experience. Of the 77 patients who underwent postoperative cystograms, reflux resolution was confirmed in 72 of 77 (94%). The failures were all in the first 30 patients of the series, with no reported failures in the last 47 patients.

Although open surgical correction of reflux is still the gold standard against which the endoscopic and laparoscopic approaches are compared, the technical advances and improved results achieved using minimally invasive techniques are gradually becoming more enthusiastically endorsed.

KEY POINTS: SURGICAL MANAGEMENT

- Exclude secondary reflux.
- The success rate of open surgical correction is very high.
- Adequate ureteral mobilization and protection of the ureteral blood supply are essential.
- A generous submucosal tunnel should be fashioned.
- Attention should be directed to avoid angulation and twisting.
- Attention to muscular backing is important.
- Bladder mucosa must be handled gently.
- Always consider bladder and bowel function preoperatively, as well as in all cases of persistent or recurrent reflux.
- Until appropriate prospective studies prove otherwise, indications for correction of reflux are the same regardless of whether the planned approach is open, endoscopic, laparoscopic, or robotic.

Bladder and Urachal Development

Classification of Bladder Anomalies

Conclusion

Although anomalies of the urogenital tract are among the most commonly diagnosed antenatal malformations, the incidence of all congenital bladder anomalies is low (Carrera et al, 1995). Additionally, bladder anomalies are often a reaction to infravesical obstruction or part of a more serious disorder rather than a true isolated structural malformation. Bladder anomalies can be severe, cause urinary obstruction, and even lead to renal failure. Early detection and intervention are crucial to prevent future decompensation of the genitourinary tract. Anomalies can be detected prenatally or postnatally using ultrasound, but often require voiding studies for definite diagnosis. This chapter reviews congenital bladder abnormalities in the prenatal and postnatal periods and focuses on malformations not caused by infravesical obstruction. This chapter includes a discussion of the initial manifestation, diagnosis, and current treatment options for the different entities and a classification based on the prenatal and postnatal manifestations of bladder anomalies.

BLADDER AND URACHAL DEVELOPMENT

A comprehensive understanding of the embryologic development of the bladder and urachus is mandatory to correctly interpret the prenatal and postnatal findings and to counsel the parents toward optimal management.

Between the 4th and 6th weeks of gestation, the urorectal septum divides the endodermal cloaca into a ventral urogenital sinus and a dorsal rectum. The cranial part of the urogenital sinus is continuous with the allantois and develops into the bladder and pelvic urethra. The caudal portion gives rise to the phallic urethra in males and the distal vagina in females. Unlike in males, the entire female urethra is derived from the pelvic part of the urogenital sinus. The allantois develops as an extraembryonic cavity from the yolk sac and connects with the cranioventral portion of the cloaca, the future bladder. Around the 4th to 5th month of gestation, the allantoic duct and ventral cloaca involute as the bladder descends into the pelvis. The descent causes the allantoic duct to elongate because it does not grow with the embryo. This epithelialized fibromuscular tube continues to become narrower until it obliterates into a thick fibrous cord, the urachus (Moore, 1982). The obliterated urachus becomes the median umbilical ligament and connects the apex of the bladder with the umbilicus (Nix et al, 1958).

Normal Antenatal Sonographic Findings of the Bladder

The fetal bladder manifests as an elliptical structure filled with anechoic fluid within the pelvis. It is bordered laterally by the umbilical arteries. The pubic bones mark the anterior border and the rectosigmoid the posterior border. The bladder wall thickness should not exceed 3 mm, and the mucosa and musculature have an echogenicity similar to that of other structures in the pelvis

(McHugo and Whittle, 2001). The bladder can be visualized in approximately 50% of cases in the fetal pelvis at the 10th week of gestation, concurrent with the onset of urine production (Green and Hobbins, 1988). The detection rate increases with fetal age to 78% at 11 weeks, 88% at 12 weeks, and almost 100% at 13 weeks (Rosati and Guariglia, 1996). Compared to abdominal ultrasound, transvaginal ultrasound increases the quality of the obtained images as well as the detection rate. The fetal bladder empties every 15 to 20 minutes; therefore a second ultrasound in the same setting is mandatory in case of nonvisualization of the bladder. The bladder's diameter increases during the first trimester but should not be more than 6 to 8 mm.

The fetal sex, the amount of amniotic fluid, and the appearance of the umbilical cord become increasingly important in the interpretation and differential diagnosis of abnormal bladder findings. Fetal sex is difficult to determine before week 14 and should not be based on the presence or absence of a phallus but on visualization of the testes (Efrat et al, 1999). The measurement of amniotic fluid as an indicator of fetal urine production is a critical portion of every antenatal ultrasound. Until 16 weeks of gestation, the amniotic fluid is mainly consistent with placental transudate, at which time it changes to predominantly fetal urine (Takeuchi et al, 1994). The umbilical cord should contain two arteries and one vein without evidence of a fluid-filled urachus (Bronstein et al, 1990).

CLASSIFICATION OF BLADDER ANOMALIES

Bladder anomalies can manifest either as abnormal findings during prenatal ultrasound or postnatally as symptoms or in an unrelated workup.

It is difficult to classify bladder anomalies because of the large variety of possible malformations, the relatively low incidence of the anomalies, and the common association with other congenital anomalies. Therefore it seems reasonable to classify the different presentations into the following two main groups:

- Prenatally detected
 - Dilated
 - Nondilated
- Postnatally detected
 - Urachal abnormalities
 - Bladder diverticulum
 - Bladder duplication
 - Other bladder anomalies

Prenatally Detected Bladder Anomalies

The fetal bladder can appear dilated, hypoplastic, or absent on ultrasound. If the bladder is dilated, the condition can be due to obstruction or caused by incomplete emptying of the bladder without evidence of a mechanical obstruction. In nondilated

conditions, the bladder is either completely absent or is unrecognizable as a fluid-filled structure because of incomplete formation.

Dilated Fetal Bladder

In the first trimester, the fetal bladder is considered dilated if larger than 7 mm on ultrasound. If, on subsequent ultrasounds, the bladder continues to retain urine and shows no evidence of urine cycling, concern regarding obstruction should be raised. If the amniotic fluid does not increase, this may indicate the progression to oligohydramnios. **Determination of the sex of the child is very important because of the male gender predominance of certain conditions and diseases such as posterior urethral valves or prune belly syndrome.** It can be difficult to distinguish in utero if the dilation is due to obstruction. In a retrospective study, [Kaefer and coworkers \(1997\)](#) described 15 patients with marked bladder dilation in utero, 8 with and 7 without obstruction. All of the patients with obstruction presented with moderate-to-severe oligohydramnios and a marked increase in renal echogenicity, whereas all but one of the nonobstructed bladders had normal amniotic fluid levels and regular renal echogenicity. Therefore fetuses with nonobstructive dilation appear to pass enough urine to maintain renal function and adequate amniotic fluid levels throughout the pregnancy ([Mandell et al, 1992](#)).

Dilation Caused by Obstruction

Urethral Anomalies and External Bladder Outlet Obstruction. Dilations of the fetal bladder caused by anatomic obstructions are mostly due to urethral anomalies or external obstruction. Urethral anomalies include congenital urethral strictures, anterior and posterior urethral valves, and urethral atresia. Compression of the bladder outlet region can be due to obstructing syringoceles, a sacrococcygeal teratoma or pelvic neuroblastoma, an anterior sacral myelomeningocele, or rectum anomalies. The observed bladder changes are due to mechanical obstruction and affect bladder development at a critical time, which can lead to bladder wall hypertrophy and remodeling ([Pagon et al, 1979](#); [Beasley et al, 1988](#); [Stephens and Gupta, 1994](#)).

Dilation in Nonobstruction

Prune Belly Syndrome and Neurogenic Bladder Disease. Affected patients do not demonstrate any sign of obstruction on postnatally performed voiding studies or cystoscopic evaluations, except when urethral atresia is also present. In this case the presentation is similar to that in patients with posterior urethral valve. However, it is possible that the largely distended bladder, as in prune belly syndrome, is caused by a transient obstruction in utero, and in some cases the presence of urethral atresia has been noted with prune belly syndrome. Another possibility for the distention is the presence of neurologic disorders leading to an inability to empty the bladder in utero.

Congenital Megacystis

The term *megacystis* is often used to describe any condition leading to a distended fetal bladder in utero, without referring to the cause of the dilation. Historically, congenital megacystis was thought to be caused by bladder neck obstruction, leading to massive bilateral vesicoureteral reflux (VUR) and a thin bladder wall ([Williams, 1957](#); [Paquin et al, 1960](#)). Even the describing authors recognized that surgical interventions at the bladder neck level did not change the future outcome. [Harrow \(1967\)](#) revisited the subject and recognized that all patients had normal urethras and complete emptying of their bladders on voiding cystourethrography (VCUG). **Therefore the observed reflux is not an after effect of obstruction but rather the cause of the bladder dilation from continuous recycling of the urine between the upper tract and bladder** ([Harrow, 1967](#)). Congenital megacystis is defined currently as a dilated, thin-walled bladder with a wide and poorly developed trigone. The

Figure 138-1. Megacystis. Vesicoureterogram image of congenital megacystis with associated reflux.

wide-gaping ureteral orifices are displaced very laterally, causing massive reflux ([Fig. 138-1](#)). Bladder contractility is normal, although a majority of the urine refluxes into the ureters with each void. No neurogenic abnormalities are described. Most patients are recognized prenatally and should be placed on prophylactic antibiotics after birth ([Mandell et al, 1992](#)). **Correcting the reflux often restores normal voiding dynamics and should be performed after 6 months of age.** Reduction cystoplasty can be performed but is usually unnecessary ([Burbige et al, 1984](#)). Although the bladder is large enough to accommodate the tapered ureters even in a young infant, the operation can be very difficult because of the bladder wall's thinness. Anterior urethral valves also have been associated with megacystis, with improvement after valve resection ([Confer et al, 2010](#)).

Congenital megacystis has been recognized in association with microcolon-intestinal hypoperistalsis syndrome. This syndrome is a rare congenital disorder characterized by a dilated, nonobstructive urinary bladder and hypoperistalsis of the gastrointestinal (GI) tract. The syndrome can be identified on antenatal ultrasound by the appearance of a largely dilated bladder. It has been reported mostly in females and is usually considered lethal ([Srikanth et al, 1993](#); [Lashley et al, 2000](#)). So far only 10 patients have lived beyond the first year of life, and almost all need total parental nutrition. Once identified after birth, the distended bladder requires drainage by intermittent catheterization or vesicostomy placement. Long-term data concerning the urinary tract are not available because of the short life span of the patients ([Bloom and Kolon, 2002](#)).

Nondilated or Absent Fetal Bladder

To truly diagnose an absent fetal bladder on ultrasound, the examination has to be repeated after 15 to 20 minutes to rule out that the fetus has not simply emptied the bladder.

Cloacal and Bladder Exstrophy. Bladder exstrophy conditions are characterized by the presence of a bladder template only. Therefore it can be suspected in the absence of regular bladder filling during fetal ultrasound. Bladder exstrophy can be distinguished from bladder agenesis by the bladder template on the lower abdominal wall, which, along with the amniotic fluid level,

remains normal throughout the pregnancy (Mirk et al, 1986; Gearhart et al, 1995).

Bladder Hypoplasia. The bladder can be hypoplastic as a result of inadequate filling or storing of urine during fetal life. Although the bladder is formed during fetal development and can be detected on antenatal ultrasound throughout pregnancy, it never reaches an adequate capacity. Conditions caused by inadequate bladder outlet resistance (e.g., severe epispadias), separation defects (e.g., urogenital sinus abnormalities), abnormalities of renal development (e.g., bilateral renal dysplasia or agenesis), or urine bypassing the bladder (e.g., ureteral ectopia), all can lead to underdevelopment of the fetal bladder. Some of these bladders grow once the malformation is corrected; however, later bladder augmentation is often required to reach adequate capacity (Gearhart, 2002).

Bladder Agenesis. Embryologic development of bladder agenesis remains difficult to explain. The division of the cloaca into the urogenital sinus and the anorectum apparently is regular, because the hindgut is usually normal. Therefore the defect can be due to either atrophy of the cranial part of the urogenital sinus or failure to incorporate the mesonephric ducts and ureters into the trigone (Krull et al, 1988). The absence of the bladder is often associated with neurologic, orthopedic, or other urogenital anomalies such as renal dysplasia or agenesis or absence of the prostate, seminal vesicles, penis, and vagina (Aragona et al, 1988). It is a very rare anomaly; only 16 live births have been reported in the 45 known cases in the English literature. All but 2 were female (Adkes et al, 1988; Gopal et al, 1993; Di Benedetto et al, 1999). The defect is compatible with life only if the ureters drain ectopically into normally developed müllerian structures in the female or in the rectum in males. In surviving infants, the diagnosis can be confirmed by retrograde ureteronephrograms via the ectopic openings. Renal function can be preserved after creation of a ureterosigmoidostomy or external stoma (Glenn, 1959; Berrocal et al, 2002).

KEY POINTS: PRENATALLY DETECTED BLADDER ANOMALIES

- Prenatally detected bladder anomalies can be categorized into dilated and nondilated anomalies.
- Dilated bladders can be caused by anatomic or functional obstruction. They are commonly associated with severe anomalies, are often the cause for oligohydramnios, and can require fetal or immediate postnatal intervention to prevent fetal demise.
- Nondilated anomalies are associated with the most severe forms of congenital urologic malformations, such as bladder and cloacal exstrophy. Usually normal amniotic fluid levels are found.
- Bladder agenesis is compatible with life only if the ureters drain ectopically.

Postnatally Detected Bladder Anomalies

The malformations in this group can be diagnosed by antenatal ultrasound. However, most patients are diagnosed postnatally because of symptomatic disease or during workup for a nonrelated disease. Malformations listed in the prenatally detected group usually severely affect fetal development, are often associated with other malformations, and require prenatal or postnatal interventions. Postnatally detected defects, on the other hand, usually do not affect fetal development and generally can be treated with conservative measures or a single surgical intervention. Bladder anomalies in the infant or child are suspected in cases of urinary tract infections, hematuria, voiding difficulties, anatomic malformations and masses, or umbilical site drainage.

Urachal Anomalies

Understanding the embryologic development of the urachus and its unique location is the key to understanding congenital urachal

Figure 138-2. Urachal anatomy. (From Cullen TS. *Embryology, anatomy and diseases of the umbilicus*. Philadelphia: Saunders; 1916.)

anomalies. The urachus is located pre-peritoneally in the center of a pyramid-shaped space. This space is lined by the obliterated umbilical arteries, with its base on the anterior dome of the bladder and the tip directed toward the umbilicus (Fig. 138-2). The urachal length varies from 3 to 10 cm. It has a diameter of 8 to 10 mm and can connect with one or both obliterated umbilical arteries. Microscopically, three layers can be identified. An inner layer consists of either transitional or cuboidal epithelial cells surrounded by a layer of connective tissue. A smooth muscle layer in continuity with the detrusor muscle composes the outer layer. Because the urachus is surrounded by the umbilicovesical fascia, disease processes usually remain contained inside the pyramid-shaped space (Hammond et al, 1941). The urachus can remain either completely open or obliterate partially, leading to the formation of cystic structures at any site throughout its course.

Ashley and associates (2007) examined the medical records of 176 patients diagnosed with a urachal anomaly, and urachal remnants were found in 46 children and 130 adults. Children mostly presented with umbilical drainage or on physical examination, and 74% underwent excision. Of the adults, 66% had hematuria or pain and 90% underwent excision. Surgical treatment in children consisted of simple excision, whereas over 50% of adults required partial or radical cystectomy because of malignancy. They concluded that urachal anomalies manifest and progress differently in

pediatric and adult populations and recommended urachal excision in early childhood to prevent later problems or cancer formation. There was no reported evidence that a persistent urachal remnant in childhood was the cause of later cancer development (Ashley et al, 2007). Galati and colleagues (2008) reported 23 children with urachal remnants, of which 10 underwent excision because of symptomatic problems. In their treatment protocol, asymptomatic remnants are managed with physical and sonographic examination. They found that spontaneous resolution with nonoperative management is likely with remnants in patients younger than 6 months. However, if symptoms persist or the remnant fails to resolve after age 6 months, they recommend excision. The following four different urachal anomalies have been described (Fig. 138-3):

1. Patent urachus (50%)
2. Umbilical-urachus sinus (15%)
3. Urachal cyst (30%)
4. Vesicourachal diverticulum (3% to 5%)

Patent Urachus

Patent urachus is explained by nondescent of the bladder or, more commonly, failure of the epithelial-lined urachal canal to obliterate (Gearhart, 2002). Bladder obstruction during fetal development has been blamed for the urachus remaining tubular. The fact that urachal patency is often absent with severely obstructed bladders in utero, however, casts doubt on this theory. Additionally, only up to 14% of patients with a patent urachus have postnatal confirmation of in utero bladder obstruction (Schrenck and Campbell, 1972; Mesrobian et al, 1997). It seems possible that obliteration of the urachus may be independent from the level of bladder distention. Therefore retubularization, rather than primary patency, might be the cause for urinary drainage from the umbilicus. This theory is supported by reports of umbilical urinary fistulas in acquired

bladder obstructions later in life (Schubert et al, 1983; Berman et al, 1988).

A patent urachus is suspected in the neonatal period by continuous or intermittent drainage of fluid from the umbilicus. The most common organisms cultured from the umbilical drainage include *Staphylococcus aureus*, *Escherichia coli*, *Enterococcus*, *Citrobacter*, and, rarely, *Proteus* species (Mesrobian et al, 1997). Additional manifestations include an enlarged or edematous umbilicus and delayed healing of the cord stump (Razvi et al, 2001; Schiesser et al, 2003). The diagnosis is confirmed by demonstration of the fluid-filled canal on longitudinal ultrasound or contrast filling on retrograde fistulogram or VCUG (Fig. 138-4) (Mesrobian et al, 1997). Computed tomography (CT) scans can aid in the diagnosis but usually depend on the bladder's filling status. It is important to differentiate the condition from a patent omphalomesenteric duct. The presence of both anomalies in the same patient is rare (Mendoza et al, 1968).

Management of an infected urachus with abscess formation includes initial drainage under antibiotic coverage. Once the infection has subsided, complete excision of the patent urachus, including a bladder cuff, is required (Nix et al, 1958). It is important to remove all anomalous tissue. This avoids recurrences or stone formation and prevents the rare event of later transformation into a malignant adenocarcinoma (Blichert-Toft and Nielson, 1971; Sheldon et al, 1984; Goldman et al, 1988; Upadhyay and Kukkady, 2003).

Traditionally, the patent urachus is surgically excised using a transverse or midline infraumbilical incision. Before surgery, a balloon catheter is used to distend the bladder. In infants, a small transverse subumbilical incision is often possible because the bladder dome is still high. A feeding tube or small catheter is placed into the patent urachus for better intraoperative identification. The urachus can be incised circumspectly, without removing

Figure 138-3. Urachal anomalies. A, Patent urachus. B, Urachal cyst. C, Umbilical-urachus sinus. D, Vesicourachal diverticulum.

Figure 138-4. Patent urachus. Vesicoureterogram image of patent urachus in a newborn. Retrograde contrast filling of patent canal with contrast pooling in umbilicus.

the umbilicus for cosmetic reasons. The rectus fascia is incised in a longitudinal fashion, muscles spread apart, and the dome of the distended bladder identified. The urachus is identified and isolated, and a vessel loop is placed. The dissection continues extraperitoneally toward the umbilicus until the previously incised umbilical portion is free and can be pulled into the surgical field. It is then removed. A bladder cuff including the urachal insertion is marked and excised using electrocautery. The bladder is closed watertight in two layers. The catheter can be left in place overnight and removed the following morning.

Alternatively, urachal remnants can be removed laparoscopically. This can be done even in children younger than 6 months of age (Fahlenkamp et al, 1995; Cadeddu et al, 2000; Khurana and Borzi, 2002). Khurana and Borzi (2002) described their laparoscopic experience with 4 children between 5 months and 10 years and found the procedure to be safe in children of all ages. Technically, they suggested a three-port approach, with the camera port in the midline between the umbilicus and the xiphoid and two working ports on either side in the upper quadrant. Turial and colleagues (2007) reported 27 children with a median age of 4.7 years. Early in their series they inserted the camera port at the umbilicus with working ports into the right and left upper abdomen. Later they preferred to place the camera into the left lower abdominal wall, with 2-mm working ports at the left lower and upper abdomen for better visualization of the urachus at the umbilicus. They reported no intraoperative or postoperative complications, no recurrences, and a median operating time of 35 minutes. The advantage of the laparoscopic technique is the good visualization of the course of the urachus and the bladder dome. However, the laparoscopic techniques require an intra-abdominal approach and pose the potential risk for spilling infected or malignant material into the abdominal cavity. Robotic-assisted removal and single-port laparoscopy also have been suggested.

Umbilical-Urachus Sinus

In the umbilical-urachus sinus, the urachus obliterates at the bladder level but remains open at the umbilical site, causing a continuously draining sinus. The manifestation is similar to that of the patent urachus. The diagnosis is made by sinugram. The caudal part of the urachus is filled with desquamated epithelial cells, and no connection to the bladder can be identified. The presence of a persistent omphalomesenteric duct has to be considered. This

would manifest as a Meckel diverticulum connected to the umbilicus. These structures can be very difficult to differentiate from an umbilical-urachus sinus because no connection to the bladder or bowel can be seen on sinugram. However, the surgical approach to both anomalies requires the complete excision of all tissue. Unlike urachal structures, omphalomesenteric remnants can show gastric or small bowel mucosa on histologic examination.

Urachal Cyst

There is no communication of the cyst with the bladder or umbilicus. However, the fluid-filled cyst can drain through the umbilicus or into the bladder intermittently. Urachal cysts are found more commonly in the distal part of the urachus and manifest more commonly in adults than in infants or children (Cilento et al, 1998). The cyst material consists of desquamated epithelial cells. These cells can become infected; *Staphylococcus aureus* has been identified as the most common organism (Mesrobian et al, 1997).

Once infected, urachal cysts can manifest as umbilical abscess formation or bladder infections. Additional symptoms include localized lower abdominal pain, voiding symptoms, or even a painful and palpable mass. The diagnosis is confirmed by ultrasound, demonstrating the localized cyst between the anterior abdominal wall and the peritoneum. In a case of massive infection or difficult manifestation, a CT scan can clarify the anatomy and extent of disease (Berrocal et al, 2002). If unrecognized, the infected cyst can perforate into the bladder (Maruschke et al, 2003) or peritoneal cavity. This can cause peritonitis and formation of an enteric fistula (Ohgaki et al, 2003; Quek et al, 2003). Treatment consists of draining the infected cyst, followed by complete excision of the urachal remnant structures.

Vesicourachal Diverticulum

The urachus obliterates almost completely, except at the level of bladder apex. Here it forms a diverticulum of varying size. These lesions are usually nonsymptomatic and found incidentally on nonrelated radiographic workups. Although the diverticulum can enlarge in the case of urinary obstruction, this rarely causes problems because they tend to have a large opening and drain into the bladder well. Stone formation and urinary tract infections have been reported, especially in the case of a narrowed neck causing the need for intervention.

KEY POINTS: URACHAL ANOMALIES

- Urachal anomalies are usually detected postnatally because of umbilical drainage.
- Infected urachal remnants are initially treated with drainage and antibiotics, followed by surgical excision. Conservative treatment with observation is justified in asymptomatic cases because of possible spontaneous resolution.
- Imaging possibilities include ultrasound, CT, and VCUG.
- Nonresolved urachal remnants should be excised because of the increased risk for later adenocarcinoma formation.

Bladder Diverticulum

Bladder diverticula are caused by infravesical obstruction, iatrogenic after bladder surgery, or as a congenital defect. Independent from the cause, all diverticula develop as herniation of bladder mucosa between defects of bladder smooth muscle fibers. The neck of the resulting diverticulum depends on the size of the muscular defect. The incidence is reported to be low, with 1.7% in a selected pediatric population of children undergoing radiographic evaluation for symptomatic disease (Blane et al, 1994). In adult males the incidence tends to be much higher because of the higher occurrence of infravesical obstruction. The

Figure 138-5. Primary paraureteral diverticulum. A, Vesicoureterogram image of large primary paraureteral diverticulum. B, Ultrasound image of the same diverticulum.

true incidence in children is difficult to evaluate, because many of the congenital diverticula remain asymptomatic and are probably never detected.

In his landmark article from 1961, Hutch describes the following two kinds of diverticula at the ureteral hiatus:

- **Primary paraureteral diverticula** are seen in smooth-walled bladders, occur isolated with no other diverticula, are intermittent in manifestation, and happen in children with no infravesical obstruction.
- **Secondary paraureteral diverticula** are found in trabeculated bladders as one of many diverticula in the bladder, are always present, and are caused by infravesical obstruction.

Primary diverticula arise as a localized herniation of bladder mucosa through the ureteral hiatus between the intravesical ureter and the roof of the ureteral hiatus. These primary diverticula are also known as *congenital diverticula* and are most likely caused by a congenitally deficient bladder wall (Fig. 138-5). Some authors have implied an isolated defect in the Waldeyer sheet; however, congenital diverticula often occur on one side only and a unilateral defect seems unlikely (Stephens, 1963). Congenital diverticula are often found in children with generalized connective tissue diseases such as Ehlers-Danlos, Williams elfin-facies, or Menkes syndrome (Babbitt et al, 1979; Daly and Rabinovitch, 1981; Levard et al, 1989). These diverticula can be resected if symptomatic; however, because of the impaired healing in patients with connective tissue disease, recurrence and wound healing complications are more common.

Secondary paraureteral diverticula are acquired and develop as a result of existing infravesical obstruction. The resulting increased infravesical pressure forces the bladder mucosa to bulge between the muscle fibers. These diverticula are usually just one of many pop-off mechanisms that can occur throughout the bladder. These diverticula also can be caused by weakening in the bladder muscle by infection (Barrett et al, 1976) or development of a muscular defect after bladder surgery (Sheu et al, 1998).

In both types of paraureteral diverticula, the Waldeyer sheet eventually becomes damaged as the diverticulum expands in size. The increasing diverticulum pulls the intravesical ureter out of its anchored position, causing dysfunction of the ureterovesical junction. Eventually, the enlarged diverticulum can become responsible for ureteral obstruction. This even has been associated with renal dysplasia (Amar, 1972; Livne and Gonzales, 1985).

Paraureteral diverticula or diverticula located in the lower part of the bladder can become so large that they compress the bladder

neck or posterior urethra. The resulting bladder outlet obstruction starts a vicious circle by continuously filling and expanding the diverticulum. This increases the obstructing and subsequently causes complete urinary retention (Sheldon and Essig, 1994; Zia-Ul-Miraj, 1999).

Bladder diverticula can be detected on prenatal ultrasound (Gaudet et al, 1999), but are mostly discovered during workup for infection, hematuria, incontinence, or obstruction. They can be suspected during ultrasound examination, especially if the bladder is viewed in different filling stages. The gold standard remains VCUG, which will reveal possible accompanying VUR. If no VUR is present, an intravenous pyelogram (IVP) with oblique views can help determine the relationship of the ureter with the diverticulum if there is hydronephrosis. Alternatively, nuclear renal studies can be used to obtain information concerning anatomy, kidney function, and ureteral obstruction. It is important to remember that congenital diverticula can have a dynamic nature and might not be present on every study. Radiographic studies may need to be repeated in cases of continuous clinical suspicion.

Small, asymptomatic congenital diverticula detected during unrelated workups can be treated conservatively with regular observation. Many surgeons tend to recommend excision of paraureteral diverticula if they are accompanied by VUR. Girls will show spontaneous resolution of their diverticula in association with VUR more frequently than boys. In his review of 304 patients with VUR, Amar (1972) confirmed the lesser resolution rate in boys. He attributed it to higher voiding pressures even without the presence of infravesical obstruction.

In acquired bladder diverticula, the infravesical obstruction has to be eliminated first. After bladder outlet resistance is normalized, the bladder can reshape and diverticulectomy might become unnecessary. If symptomatic, the diverticulum should be excised. The ipsilateral ureter should be reimplanted if it is near or included in the diverticulum. This traditionally has been performed intravesically; however, the procedure can be safely performed by an extravesical approach (Jayanthi et al, 1995; Yu, 2002). Laparoscopic excision also has been successfully performed in a 6-year-old child (Kok et al, 2000). Endoscopic subureteral injection of dextranomer/hyaluronic acid (Deflux) has been used for the correction of VUR, even in the presence of a primary paraureteral diverticulum (Perez-Brayfield et al, 2004). Robotic-assisted diverticulectomy in 14 patients was reported and described as a safe alternative to open surgery (Christmas and Casale, 2012).

KEY POINTS: BLADDER DIVERTICULUM

- Bladder diverticula can be detected on prenatal ultrasound, but the gold standard remains VCUG, which will reveal possible accompanying VUR.
- Primary diverticula arise as a localized herniation of bladder mucosa at the ureteral hiatus and are most likely caused by a congenitally deficient bladder wall.
- Secondary paraureteral diverticula are acquired and develop as a result of existing infravesical obstruction.
- Symptomatic diverticula, especially in conjunction with VUR, should be treated surgically.

Bladder Duplication

Duplication of the bladder and urethra can be complete or incomplete. It can occur in either the coronal or sagittal plane. [Abrahamson \(1961\)](#) attempted to classify the various bladder duplication anomalies and found complete duplication in the sagittal plane the most common. In incomplete duplications, the two bladder halves communicate and are usually drained by a single urethra. In complete duplications, the two bladders are fully separated entities with normal mucosa and a full-thickness musculature wall divided by a peritoneal fold ([Fig. 138-6](#)). Although the size and quality of each entity can be different, they are usually supplied with their own ureter and are drained by an individual urethra and external meatus ([Esham and Holt, 1980](#)). In rare cases, one bladder can lack a urethra. This leads to ipsilateral renal dysplasia via complete obstruction ([Cheng and Maizels, 1996](#)). Both bladders may possess a sufficient continence mechanism, or one side may be compromised, causing incontinent episodes.

Associated duplication anomalies of the external genitalia have been reported in up to 90% of cases; associated duplication anomalies of the lower GI tract have been reported in up to 42% of cases ([Kossow and Morales, 1973](#)). Duplicated vaginas can be connected to a separate unicornuate uterus. Duplicated penises are supplied with an individual urethra. Additional urologic abnormalities such as VUR, renal ectopia, or dysplasia are commonly found. Association with other nonurologic congenital anomalies are more frequent in sagittal than coronal duplications. Multiple manifestations have been described, including GI malformations,

duplications of the spine, spina bifida conditions, and various fistula formation between the urogenital and GI tract ([Berrocal et al, 1999](#)). In duplication variations of the classic cloacal-bladder exstrophy complex, patients present with an exstrophic bladder and urethra in addition to a closed regular intra-abdominal bladder ([Perren and Frey, 1998](#)).

The embryologic development of the various duplication anomalies remains poorly understood. Complete duplication of the bladder and hindgut is thought to occur as a result of partial twinning of the tail portion of the embryo ([Ravitch and Scott, 1953](#)). It also is suggested that the development of a sagittal fissure on the cloacal plate occurs when the urorectal septum separates the urogenital from the digestive sinus ([Bellagha et al, 1993](#)).

The wide range of anatomic manifestations of duplicate bladders explains the different time points and modes of manifestation. With associated malformations of the GI tract or external genital tract, the diagnosis is often made in the newborn period. However, many children are not diagnosed until recurrent infections or incontinence initiates a urologic workup. Although similarities exist, each case is different and warrants individual management. Complete preoperative diagnostic evaluations with karyotype, ultrasound, IVP, videourodynamic studies, genitogram, and GI tract imaging are useful to determine the anatomic situation. VCUG and nuclear renal scans can supply additional information regarding VUR and renal function. Complete understanding of the various anomalies can be very difficult. Often the final treatment plan has to be deferred until the time of endoscopic and surgical exploration of the malformation. **Initial treatment is directed toward renal preservation and prevention of infections by relieving possibly obstructed genitourinary tracts.** Long-term goals include achieving continence and reconstructing the internal and external genitalia. Incomplete duplications may not require surgical procedures if both bladder halves are sufficiently drained by a common urethra. In complete duplications, the two bladders can be combined into one. If both sphincter complexes are competent, the distal urethras are connected. If one is incompetent, the corresponding bladder neck can be closed and the connected urethra excised. Duplicated vaginas are combined in the midline, and a vulvoplasty is performed. The urogenital duplications also can be left uncorrected if the patient is asymptomatic; [Gastol and associates \(2000\)](#) reported two successful pregnancies in a 26-year-old woman. Because of the rarity of the disease and the large variety of manifestations, the surgeries must be individualized and should be performed in centers experienced in complex urogenital reconstruction.

Figure 138-6. Complete bladder duplication. A, Vesicoureterogram image of complete bladder duplication with catheters inserted into each individual urethra. Note the size discrepancy. B, Ultrasound image of the same patient.

Figure 138-7. Eosinophilic cystitis. A, Cystoscopic views of lesion detected as mass on ultrasound in teenage male with severe dysuria and gross hematuria. B, Biopsy of mucosal lesion demonstrating eosinophilic infiltrate and no evidence of malignancy.

KEY POINTS: BLADDER DUPLICATION

- Bladder duplication is often associated with duplication anomalies of the external genitalia and lower GI tract.
- Initial treatment is directed toward renal preservation and prevention of infections by relieving possibly obstructed genitourinary tracts.
- Long-term goals include achieving continence and reconstructing the internal and external genitalia.
- Because of the rarity of the disease and the large variety of manifestations, the surgeries must be individualized.

Other Bladder Anomalies

Nephrogenic Adenoma

Nephrogenic adenoma of the urinary bladder is a rare benign tumor mostly found in adults. Sporadic case reports in children describe the lesion as a reaction to infection, lithiasis, or trauma or in response to surgery. [Heidenreich and coworkers \(1999\)](#) found a significant predominance of girls compared to boys (5:1), typically presenting with hematuria or irritative bladder symptoms. The diagnosis is established after cystoscopy with biopsy. Treatment consists of transurethral fulguration or resection and can be combined with long-term antibiotic prophylaxis. Although malignant transformation was not reported, tumor recurrence developed in 80% of the children, with a latency period of 4 years. Resection of nephrogenic adenoma followed by successful long-term resolution using ibuprofen and trimethoprim-sulfamethoxazole also has been described ([Voss and Peppas, 2013](#)).

[Hungerhuber and colleagues \(2008\)](#) reported a rare case of an adenocarcinoma in a 25-year-old patient who developed a nephrogenic bladder after a car accident. He subsequently developed a nephrogenic adenoma, which was resected several times. Although the initial pathologic finding was benign, a moderately differentiated adenocarcinoma was found after several resections. He underwent a radical cystectomy and remained tumor-free.

[Kao and associates \(2013\)](#) reviewed 21 cases of nephrogenic adenomas from urinary bladder biopsies. Most patients had a history of bladder augmentation with recurrent stone formation and infections. The immunohistochemical profile suggested that nephrogenic adenomas are derived from distal tubular cells.

Eosinophilic Cystitis

Eosinophilic cystitis in children is sporadically described in case reports with a predominance in boys. **The cause remains unclear,**

and the histopathologic examination includes inflammatory cells with numerous eosinophils throughout all layers of the bladder wall ([Tsakiri et al, 2004](#)). Manifesting symptoms include dysuria, hematuria, suprapubic pain, and urinary retention. It can be detected on ultrasound, but the diagnosis is made by cystoscopy with transurethral biopsy of the lesion ([Fig. 138-7](#)). Immunologic diseases and allergies have been suggested to be causative for the development of the lesions. In his large review of 135 cases, van den [Ouden \(2000\)](#) found transurethral resection combined with corticosteroids, antihistaminics, or antibiotics to be most successful for all age groups. In neonates and young children the disease can be self-limited and observation is justified ([Al-Omar et al, 2005](#)). In a case series of 4 patients between 5 days and 18 years, all were diagnosed by biopsy after clinical suspicion and were successfully treated with a combination of steroids, antihistamines, and antibiotics ([Sparks et al, 2013](#)).

Bladder Hemangioma

These benign vascular tumors are mostly seen in association with Klippel-Trenaunay syndrome and can be solitary or in multiple locations throughout the bladder. The leading symptom is macrohematuria and the vascular tumors are found during cystoscopy. Treatment consists of neodymium:yttrium-aluminum-garnet (Nd:YAG) laser irradiation of the affected areas ([Kato et al, 2000](#)).

Bladder Hernia

In rare cases the bladder has been found in hernia sacs during a routine hernia repair. It can be suspected in an unusual large hernia sac, urine drainage during or after surgery, or the new onset of hematuria postoperatively. [Manatt and associates \(2006\)](#) reported a bladder hernia in a premature infant found during a cystogram performed because of hydronephrosis. The bladder was reduced during hernia repair, and no further problems were encountered.

CONCLUSION

Isolated congenital bladder anomalies are very rare. Most published information relies on case reports of various malformations and their individualized management. Many of the detected anomalies are due to infravesical obstruction or are part of a syndrome affecting other parts of the genitourinary or nonurologic systems. Prenatal ultrasound allows early detection of bladder changes and has vastly influenced the prenatal and postnatal management of the described malformations. However, because of the rarity of the various manifestations, large series with adequate follow-up are

missing. Management and treatment remain individualized. Severe anomalies are often difficult to understand, and treatment should be centralized in specialized centers.

EXSTROPHY-EPISPADIAS COMPLEX

The exstrophy-epispadias complex of genitourinary malformations can be as simple as a glanular epispadias or an overwhelming multisystem defect such as cloacal exstrophy (Fig. 139-1). This chapter provides a comprehensive overview of the entire bladder exstrophy-epispadias-cloacal exstrophy spectrum. In addition, all modern methods of exstrophy management and their complications and outcomes are discussed.

Historical Aspects

In older texts, the first account of bladder exstrophy was ascribed to Assyrian-Babylonian sources dating from the first and second millennia BCE. At that time, birth anomalies in both humans and animals were carefully recorded on tablets for their importance as omens, based on their interpretation by divination experts. Feneley and Gearhart (2000) examined Assyrian-Babylonian descriptions of congenital anomalies from cuneiform texts at the British Museum in London. Although references to anomalies involving the external genitalia were frequent (e.g., hermaphroditism, absence of external genitalia, unilateral and bilateral undescended testes), references to renal and bladder anomalies were few and difficult to interpret medically. Duplication and laterality of anomalies were described in detail owing to their distinct significance, but malformations in combination were not recorded. On the basis of these studies performed with a prominent Assyriologist, a definitive description of bladder or cloacal exstrophy was not corroborated. The first described case of epispadias is attributed to the Byzantine emperor Heraclius (610-641 CE), and the first description of cloacal exstrophy to Schenck in 1595 (Feneley and Gearhart, 2000).

Incidence and Inheritance

Data from the International Clearinghouse for Birth Defects monitoring system estimated the incidence to be 2.2 cases in 100,000 live births (Siffel et al, 2011). The male-to-female ratio of bladder exstrophy derived from multiple series is 2.3:1 (Shapiro

et al, 1984). However, two series reported a 5:1 to 6:1 male-to-female ratio of exstrophy births (Ives et al, 1980; Lancaster, 1987).

The risk of recurrence of bladder exstrophy in a given family is approximately 1 in 100 (Ives et al, 1980). Shapiro and colleagues (1985) in a questionnaire identified the recurrence of exstrophy and epispadias in only 9 of approximately 2500 indexed cases. Lattimer and Smith (1966) cited a set of identical twins with bladder exstrophy and another set of twins in whom only one child had exstrophy. Shapiro's series identified five sets of male and female nonidentical twins in whom only one twin was affected with exstrophy; five sets of male identical twins in whom both twins were affected; one set of identical male twins in whom only one twin was affected; and three sets of female identical twins in whom only one twin had the exstrophy anomaly (Shapiro et al, 1984). Reutter and coworkers (2003) have demonstrated six families with two occurrences of the exstrophy-epispadias complex, one in which the proband was the product of a consanguineous union and four discordant twin pairs. Also, Boyadjiev and colleagues (2004a) found four multiplex families (2.7%) in a cohort of 151 families with the exstrophy-epispadias complex. There were three twin pairs, two of which were monozygotic, and concordance was present in only one of the twin pairs. Consanguinity was present in one family. Bladder exstrophy or epispadias was not reported until the 1980s in the offspring of parents with the exstrophy-epispadias complex. Shapiro and colleagues (1984) determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is 1 in 70 live births, a 500-fold greater incidence than in the general population. Boyadjiev and colleagues (2004a) studied sibling data from 200 families and found 259 unaffected children in addition to the probands with exstrophy. Twenty-six probands had first-, second-, or third-degree relatives with congenital anomalies unrelated to the exstrophy-epispadias complex, most of which were midline defects and oral clefts. Four probands had a total of seven biologic children who were unaffected. New data from Boyadjiev and coauthors (2004a) indicates that the average maternal age for exstrophy mothers was 34 years and the average paternal age was 32 years. In addition, 49% of probands were born from first pregnancies. This may represent

Figure 139-1. Entities that constitute the exstrophy-epispadias complex. **A,** Cloacal exstrophy. **B,** Superior vesical fissure. **C,** Classic bladder exstrophy. **D,** Male epispadias. **E,** Female epispadias.

societal changes indicating advancing maternal age for first pregnancies and increased risk of exstrophy when assisted reproductive techniques are used (Wood et al, 2003).

A recent (2011) multi-institutional study from North America and Europe involving an analysis of 441 families divided the study into mild epispadias ($n = 43$), intermediate-classic exstrophy ($n = 366$), and severe (cloacal) exstrophy ($n = 31$). Males were over-represented in all groups. Cleft lip and cleft palate were seen in a high prevalence. Maternal smoking during the first trimester was associated closely with cloacal exstrophy, and maternal preconception folic acid supplementation was associated with the mildest phenotype (epispadias) (Reutter et al, 2011).

Exploration of possible causes for the exstrophy-epispadias complex continues. A report from Israel indicated a 10-fold increase in exstrophy births to mothers who had received large doses of progesterone in the early part of the first trimester.

Wood and colleagues (2003) reported on a sizable series of children with exstrophy conceived using assisted reproductive techniques. A 7.5-fold increase in incidence was noted when in vitro fertilization was used. These two reports indicate a role for hormonal changes in the etiology of the exstrophy-epispadias complex. In a large series of 214 females, no association with parental age, maternal reproductive history, or preconception maternal exposure to alcohol, drugs, radiation, or infections was found (Gambhir et al, 2008). However, preconception maternal exposure to smoking was significantly more common in patients with cloacal exstrophy than in the combined group of patients with classic exstrophy-epispadias.

Genetic studies to identify a genetic locus for the exstrophy-epispadias complex are underway. Boyadjiev and coauthors (2004b) have reported finding a breakpoint disruption in the 5' region of the *CASPR3* gene on chromosome 9. This observation is the first to suggest a possible genetic basis for development of

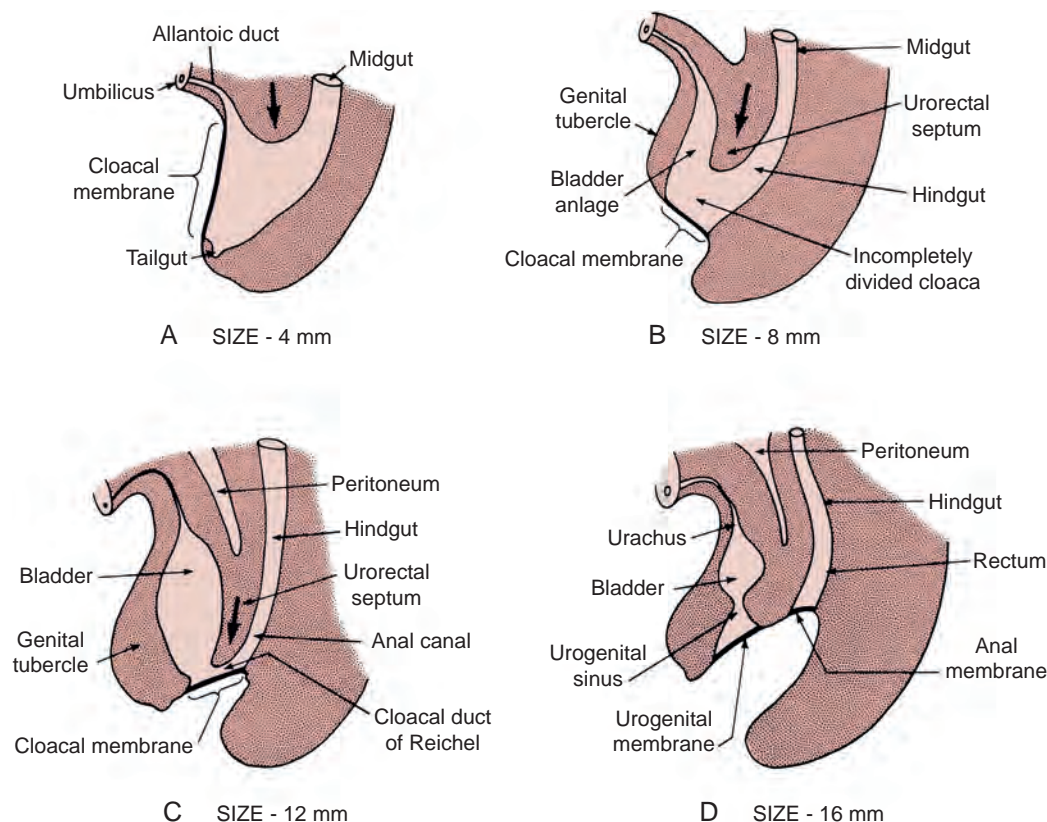

Figure 139-2. A-D, Development of the cloaca and cloacal membrane in the 4- to 160-mm embryonic stages. Caudal growth of the urorectal septum leads to separation of the anterior urogenital sinus from the posterior rectum.

the exstrophy-epispadias complex. In another recent study by Ludwig and colleagues (2009), risk loci for the exstrophy spectrum were found in seven separate chromosomes, with susceptibility genes in several regions.

Qi and colleagues (2011) used genome wide expression profiling to identify 162 bladder exstrophy-epispadias complex candidate genes that had twofold or higher expression differences between exstrophic and normal bladder smooth muscles in mouse and human embryologic bladder tissues. They also found 16 candidate genes that are expressed in the infraumbilical endoderm and mesoderm. Most of these genes have functions related to cellular assembly, musculoskeletal system development, and connective tissue morphology. Specifically, 30% of these genes were related to the desmosomal structure and cytoskeleton assembly, of which 69% were underexpressed in exstrophic bladders. In this study, the two most downregulated genes in exstrophic bladders, desmin and desmuslin, encode muscle-specific proteins that interact with desmoplakin, the sixth most overexpressed gene in exstrophic bladders. New data from Ching and colleagues (2010) and Qi and colleagues (2013) has shown significant dysregulation of p63 in tissue from newborns with bladder exstrophy.

Embryology

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy-epispadias complex (see Fig. 139-1). The cause of this complex is thought to be the failure of the cloacal membrane to be reinforced by ingrowth of mesoderm (Muecke, 1964). The cloacal membrane is a bilaminar layer situated at the caudal end of the germinal disk that occupies the infraumbilical abdominal wall. Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane results in formation of the lower abdominal muscles and the pelvic bones. The cloacal membrane is subject to premature rupture, and, depending on the extent of the infraumbilical defect and the stage of development during which

the rupture occurs, bladder exstrophy, cloacal exstrophy, or epispadias results (Ambrose and O'Brien, 1974).

After mesenchymal ingrowth occurs, the urorectal septum grows in a caudal direction and divides the cloaca into a bladder anteriorly and a rectum posteriorly (Fig. 139-2). Distally, the septum meets the posterior remnant of the bilaminar membrane, which eventually perforates and forms the urogenital and anal openings. The paired genital tubercles migrate medially and fuse in the midline, cephalad to the dorsal membrane before perforation.

The theory of embryonic maldevelopment in exstrophy held by Marshall and Muecke (1968) is that the basic defect is an abnormal overdevelopment of the cloacal membrane during the 4th week of gestation, which prevents medial migration of the mesenchymal tissue and proper lower abdominal wall development. The timing of the rupture of this defective cloacal membrane determines the variant of the exstrophy-epispadias complex that results. Classic exstrophy accounts for more than 50% of the patients born with this complex (Muecke, 1964; Marshall and Muecke, 1968). Martinez-Frias and coworkers (2001), using epidemiologic factors of low birth weight, twinning, single umbilical artery, and associated defects, postulated that cloacal exstrophy and exstrophy of the bladder are two different expressions of a primary developmental field defect, with cloacal exstrophy being an early defect. It has been postulated that one or both of the lateral body wall folds fails to move far enough ventrally to meet its counterpart in the midline (Sadler and Feldkamp, 2008). Thus, if closure fails in the abdominal and pelvic region, cloacal exstrophy results, and if failure occurs in the pelvis alone, classic exstrophy occurs.

Other plausible theories concerning the cause of the exstrophy-epispadias complex exist. Abnormal development of the genital hillocks caudal to the normal position, with fusion in the midline below rather than above the cloacal membrane, has been embraced by other investigators (Patton and Barry, 1952; Ambrose and O'Brien, 1974). Another interesting hypothesis that remains controversial describes an abnormal caudal insertion of the body stalk,

which results in a failure of interposition of the mesenchymal tissue in the midline (Mildenberger et al, 1988). As a consequence of this failure, translocation of the cloaca into the depths of the abdominal cavity does not occur. A cloacal membrane that remains in a superficial infraumbilical position represents an unstable embryonic state with a strong tendency to disintegrate (Johnston and Kogan, 1974), which has been supported by the laboratory work of Thomalla and colleagues (1985).

Maldevelopment of the bony pelvis rather than soft-tissue defects has been suggested to be the inciting issue for the development of exstrophy. Beaudoin and colleagues (1997) have suggested that lack of "rotation" of the pelvic ring primordium prevents structures attached to the pelvic ring from joining in the midline, allowing herniation of the bladder to occur. The cause of this inadequate rotation remains elusive.

CLASSIC BLADDER EXSTROPHY

Anatomic Considerations

Exstrophy of the bladder is part of a spectrum of anomalies involving the urinary tract, the genital tract, the musculoskeletal system, and sometimes the intestinal tract. In classic bladder exstrophy (CBE), most anomalies are related to defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus. Because of the involved nature of this defect, the deficits are described here as they affect each system.

Skeletal Defects

Formerly, CBE was thought only to show the characteristic widening of the pubic symphysis caused by malrotation of the innominate bones with an outward rotation or eversion of the pubic rami at their junction with the iliac bones. However, modern imaging using three-dimensional (3D) computed tomography (CT) has demonstrated previously unknown rotational and dimensional abnormalities (Sponseller et al, 1995). Rotational anomalies include (1) external rotation of the posterior pelvis/iliac wings; (2) external rotation of the anterior pelvic segment; (3) coronal rotation of the sacroiliac joint; (4) acetabular retroversion; (5) convergence of iliac wings; and (6) femoral retroversion. Dimensional anomalies include (1) increased pubic diastasis; (2) shortened anterior pubic segment; and (3) increased intertriradiate cartilage distance.

Sponseller and associates (1995), using CT of the pelvis with 3D reconstruction, were the first to accurately characterize the exact bony defect associated with both CBE and cloacal exstrophy. In reviewing a large group of patients with exstrophy of the bladder, using pelvic CT scans and age-matched controls, Sponseller and coworkers (1995) found that patients with CBE have a mean external rotation of the posterior pelvis of 12 degrees on each side, along with retroversion of the acetabulum, and a mean 18 degrees of external rotation of the anterior pelvis, along with 30% shortening of the pubic rami, in addition to the previously described diastasis of the symphysis pubis (Fig. 139-3). In long-term follow-up there was a foot progression angle of 20 to 30 degrees of external rotation beyond the normal limits seen in early childhood, which improves with age. Likewise, patients with cloacal exstrophy not only had pelvic deformities to a greater degree but also had asymmetry of the preceding parameters between the right and left sides of the pelvis, malformation of the sacroiliac joints, and occasional dislocations of the hip (Sponseller et al, 1995).

Data from Stec and associates (2001a), who used 3D models from CT scans, found the sacroiliac joint angle (before closure) was 10 degrees larger than controls in the exstrophy pelvis, being 10 degrees more toward the coronal plane than sagittal (Fig. 139-4); the exstrophy pelvis had 14.7 degrees more inferior rotation than controls. In addition, the sacrum in exstrophy patients has a 42.6% larger volume and 23.5% more surface area than in controls.

These rotational deformities of the pelvic skeletal structures contribute to the short, pendular penis seen in bladder exstrophy.

Figure 139-3. Pelvic bone abnormalities noted in classic bladder exstrophy. The posterior bone segment is externally rotated (12 degrees mean on each side), but the length is unchanged. The anterior segment is externally rotated (18 degrees mean on each side) and shortened by 30%. The distance between the triradiate cartilage is increased by 31%.

Figure 139-4. Sacroiliac joint angles before closure in children with classic exstrophy are 10 degrees larger than normal controls. The bony pelvis has 14.7 degrees of inferior rotation compared with lack of rotation. (From Stec AA, Pannu HK, Tadros YE, et al. Evaluation of the bony pelvis in classic bladder exstrophy using 3D-CT: further insights. *Urology* 2001;58:1030-5.)

Outward rotation and lateral displacement of the innominate bones also accounts for the increased distance between the hips, waddling gait, and outward rotation of the lower limbs in these children, which in itself causes little disability and usually corrects to some degree over time. The 30% shortage of bone in the exstrophy pelvis has largely gone unexplained. Studies by Stec and colleagues (2003) using sections from the bony pelvis in fetal exstrophy specimens and normal aborted fetuses found that the ultrastructure, bone development, microscopic growth patterns, and endochondral ossification were absolutely the same. Thus,

restoration of the physiologic shape of the pelvis may lead to more normal bone growth, decreased shortage of bone, and a more appropriate distribution of the mechanical and developmental forces on a more closed, normally functioning pelvic ring.

The incidence of spinal anomalies in exstrophy has not been well studied. A single study of 299 children with bladder exstrophy indicated spinal variations without clinical significance (spina bifida occulta, lumbarization or sacralization of vertebrae) in 11%, uncomplicated scoliosis in 2.7%, and spinal dysraphism in 4%, including myelomeningocele, lipomeningocele, scimitar sacrum, and hemivertebrae, but only 1 patient demonstrated any evidence of neurologic dysfunction (Cadeddu et al, 1997).

Pelvic Floor Defects

Stec and colleagues (2001b), using 3D models created from CT scans of children with CBE and normal age-matched controls, found that the puborectal slings were supporting two times more body cavity area than normal. The levator ani group is positioned more posteriorly in exstrophy patients, with 68% located posterior to the rectum and 32% anterior (vs. 52% posterior and 48% anterior in healthy controls) (Fig. 139-5). The levators are also rotated outward 15.5 degrees, and in the coronal aspect the levators are 31.7 degrees more flattened than normal. This deviation from normal makes the exstrophy puborectal sling more flattened than its normal conical shape. There was no significant difference in the length or

thickness of these muscles between patients with exstrophy and controls.

A comparison of 3D magnetic resonance imaging (MRI) in children with exstrophy before closure and normal controls indicated that the levator ani group was less dome shaped and more irregular in those with exstrophy (Williams et al, 2004). Also, there was no relationship between the amount of pubic diastasis and the extent of disproportionate curvature of the levator ani group. In addition, Halachmi and coauthors (2003) reported on the postoperative appearance of the pelvic floor with 3D MRI. In 2 patients who had some degree of continence, the intrasymphyseal distance was shortest, the angle of the levator ani divergence more normal, and the bladder neck most deeply positioned in the pelvis. Gargollo and colleagues (2005), reporting on a mixed group of patients, noted that the puborectalis angle in those with dry intervals was decreased compared with that before closure. These two studies correlate well with earlier findings of Gearhart and coworkers (1993c) showing that in the adult patients who were dry, the puborectalis angle was less than 65 degrees. Recent data, again from Stec and colleagues (2012b), used 3D MRI to evaluate the pelvis before and after primary closure. Of the 19 patients, 12 had closure as newborns without osteotomy and 7 had closure outside of the newborn period with an osteotomy. The preoperative and postoperative MRIs revealed that closure (1) reshapes the pelvis from a boxlike configuration to a more inwardly rotated hammock; (2) redistributes a significant portion of the levator group into the

Figure 139-5. A, Pelvic floor anatomy before closure of exstrophy. Osteotomy incisions marked. B, Lateral view of pelvic floor anatomy showing postdisplacement of pelvic floor muscles behind rectum. anterior compartment; and (3) facilitates a smooth uniform contouring of the pelvic floor. These data reinforce the necessity for aggressive dissection and posterior placement of the posterior vesicourethral unit into the pelvis and the role of pelvic osteotomy and pelvic fixation.

Abdominal Wall Defects

The triangular defect caused by the premature rupture of the abnormal cloacal membrane is occupied by the exstrophied bladder and posterior urethra. The fascial defect is limited inferiorly by the intrasymphyseal band, which represents the divergent urogenital diaphragm. This band connects the posterior vesicourethral unit to the pubic ramus on anatomic study. The anterior sheath of the rectus muscle has a fanlike extension behind the urethra and bladder neck that inserts into the intrasymphyseal band. Investigations into the relationship of the rectus muscle and fascia to the urogenital diaphragm (Wakim and Barbet, 2002) have found no gross or histologic evidence of the presence of the striated sphincter. However, clear evidence of bladder musculature extending laterally to the pubis was found where it interdigitates with fibers from the rectus fascia, forming the fibrous urogenital diaphragm (Wakim and Barbet, 2002). Gearhart and colleagues (1991) have shown the importance of radical incision of these fibers lateral to the urethral plate down to the level of the inferior pubic ramus and levator hiatus, and data from failed exstrophy closures show these fibers to be intact in many patients at the time of reclosure.

At the upper end of the triangular fascial defect is the umbilicus. In bladder exstrophy, the distance between the umbilicus and the anus is foreshortened. Because the umbilicus is situated well below the horizontal line of the iliac crest, there is an unusual expanse of uninterrupted abdominal skin. If an umbilical hernia is present, it is usually of insignificant size. The umbilical hernia is repaired at the time of the initial exstrophy closure. Omphaloceles frequently seen in cloacal exstrophy are rare in exstrophy and are usually small and closed at the time of bladder closure.

The frequent occurrence of indirect inguinal hernias is attributed to a persistent processus vaginalis, large internal and external inguinal rings, and lack of obliquity of the inguinal canal. Connolly and colleagues (1995), in a review of 181 children with bladder exstrophy, reported inguinal hernias in 81.8% of boys and 10.5% of girls. At the time of closure of the bladder exstrophy, these hernias should be repaired by excision of the hernial sac and repair of the transversalis fascia and muscle defect to prevent recurrence or a direct inguinal hernia. The contralateral side should also be explored because the incidence of synchronous or asynchronous bilaterality is 81.8% (Connolly et al, 1995). Recent data by Lavien and colleagues (2014) in a large group of 136 exstrophy closures clearly demonstrated that if pelvic osteotomy is used for the closure, the incidence of development of a hernia is lower and the risk of recurrence after repair is lower.

Anorectal Defects

The perineum is short and broad and the anus is situated directly behind the urogenital diaphragm; it is displaced anteriorly and corresponds to the posterior limit of the triangular fascial defect. Recent data from Stec and colleagues (2011) found in a series of 678 patients with classic exstrophy an incidence of colorectal anomalies of 1.8%. The most common anomaly was imperforate anus, second was rectal stenosis, and third was congenital rectal prolapse. Although the incidence is low, it is a 72-fold increase compared with the general population.

The divergent levator ani and puborectalis muscles and the distorted anatomy of the external sphincter contribute to varying degrees of anal incontinence and rectal prolapse. Anal continence is usually imperfect at an early age. Rectal prolapse frequently occurs in untreated exstrophy patients and is usually transient and easily reduced. Prolapse disappears after bladder closure and pubic apposition. The appearance of prolapse in an infant is an indication to proceed with definitive management of the exstrophied bladder. If

Figure 139-6. Newborn male with classic bladder exstrophy. Note the dorsal chordee, short urethral plate, and flattening of the scrotum.

rectal prolapse occurs at any time after exstrophy closure, posterior urethral or bladder outlet obstruction should be suspected, and immediate evaluation of the outlet tract by cystoscopy should be performed (Baker and Gearhart, 1998).

Male Genital Defect

The male genital defect is severe and is the most troublesome aspect of the surgical reconstruction (Fig. 139-6). Formerly, it was thought that the individual corpora cavernosa were of normal caliber but appeared shorter because of the wide separation of the crural attachments, the prominent dorsal chordee, and the shortened urethral groove. However, Silver and colleagues (1997b) described the genital defect for the first time in exacting detail. MRI was used in adult men with bladder exstrophy and compared with results for age- and race-matched controls. It was found that the anterior corporeal length of male patients with bladder exstrophy was almost 50% shorter than that of normal controls (Fig. 139-7). However, although the posterior length of the corporeal body was the same as in age-matched controls, the diameter of the anterior corporeal segment was 30% greater than normal. Also, on MRI, although the diastasis of the symphysis pubis increased the intra-symphyseal and intercorporeal distances, the angle between the corpora cavernosa was unchanged because the corporeal bodies were separated in a parallel fashion. Therefore the penis appears short not only because of the diastasis of the pubic symphysis but also because of marked congenital deficiency of anterior corporeal tissue (Silver et al, 1997b). In a recent surgical anatomic study by Perovic and Djinojic (2008), precise description of the penile defect included (1) corporeal bodies separated and triangular in shape; (2) a long convex ventral surface and a short wedge-shaped dorsal surface; and (3) neurovascular bundle length determined by its lie on the individual corporeal bodies.

Figure 139-7. Separation of the pubic bones in men with classic exstrophy combined with the congenital deficiency of the anterior corporeal tissue leads to the shorter appearance of the penis. aCC, corpora cavernosa suspended angle; ACL, anterior corporeal length; Cdiam, corpus cavernosum diameter; ICD, intercorporeal distance; ISD, intersymphyseal distance; PCL, posterior corporeal length; TCL, total corporeal length.

Figure 139-8. A, Axial T2-weighted image of the mid-prostate in a 20-year-old continent patient with bladder exstrophy. Small arrowhead, lumen of the urethra; medium arrowhead, transitional zone; large arrowhead, peripheral zone. Curved arrow, fibrous band of the intersymphyseal bar. B, Sagittal T2-weighted image through the mid-prostate gland shows anterior urethra (double arrows) and posterior prostate gland. Intersymphyseal fibrous band (curved arrow) extends along the entire length of the prostate.

In a study by Gearhart and associates (1993c), 13 adult men born with bladder exstrophy were evaluated with MRI of the pelvis to evaluate the size and configuration of the prostate and accessory sex organs. The volume, weight, and maximum cross-sectional area of the prostate appeared normal compared with published control values (Fig. 139-8). In none did the prostate extend circumferentially around the urethra, and the urethra was anterior to the prostate in all patients. Silver and coworkers (1997a) reported free and total prostate-specific antigen (PSA) levels for a group of adult men with exstrophy. Although the levels were measurable, they were below the upper limits of established age-specific reference ranges for normal men. The vas deferens and ejaculatory ducts are normal in the exstrophy patient, and the mean seminal vesicle length in men is normal compared with published controls.

Autonomic innervation of the corpus cavernosum is provided by the cavernous nerves. These autonomic nerves are displaced laterally in patients with exstrophy (Schlegel and Gearhart, 1989). These nerves are preserved in almost all exstrophy patients because potency is preserved after surgery. However, retrograde ejaculation may occur after bladder closure and/or bladder neck reconstruction.

Testis function has not been studied in a large group of postpubertal exstrophy patients, and it is generally believed that fertility is not impaired by testicular dysfunction. The testes frequently appear undescended in their course from the widened separated pubic tubercles to the flat, wide scrotum. Most testes are retractile and have an adequate length of spermatic cord to reach the scrotum without the need for orchiopexy.

Figure 139-9. Newborn girl with classic bladder exstrophy. Notice the open urethral plate, bifid clitoral halves, and anterior displacement of the vaginal orifice.

Female Genital Defects

Reconstruction of the female genitalia presents a less complex problem than in the male (Fig. 139-9). The vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly, the clitoris is bifid, and the labia, mons pubis, and clitoris are divergent. The cervix enters the vagina superiorly so that it lies in the anterior vaginal wall near the introitus. The fallopian tubes and ovaries are normal. The clitoral halves should be joined and the two ends of the labia minora joined to make a fourchette at the time of primary closure. Vaginal dilation or episiotomy may be required to allow satisfactory intercourse in the mature female. Prior data by [Stec and colleagues \(2001b\)](#) and recent 3D ultrasound data by [Ebert and colleagues \(2009\)](#) show that although the levator hiatus has a normal anteroposterior length, it is almost two times wider than normal. This defective pelvic floor may predispose mature females to the development of uterine prolapse, making uterine suspension necessary. This usually occurs after childbirth but can occur even in the nulliparous patient. When studied in a large adult female population, 10 of 56 women developed uterine prolapse at a mean age of 16 years. Six patients had been managed with reconstruction that included a posterior iliac osteotomy ([Mathews et al, 2003a](#)). Mean age at the time of osteotomy was 2.1 years. Formerly, it was thought that osteotomy in the newborn or during early childhood would be protective against the development of uterine prolapse in adult life. However, new data from [Anusionwu and colleagues \(2013\)](#) in a large group of women with exstrophy showed that the width of the adult diastasis was the only factor on univariate analysis to predict adult prolapse.

Urinary Defects

At birth, the bladder mucosa usually appears normal; but often hamartomatous polyps may be present on the bladder surface. The bladder mucosa should be frequently irrigated with saline and protected from trauma by some form of protective membrane before closure, so that cystic or metaplastic changes in the mucosal surface do not occur.

The size, distensibility, and neuromuscular function of the exstrophied bladder, as well as the size of the triangular fascial defect to which the bladder muscles attach, affect the decision to attempt repair. In the past several years, multiple basic science studies have been published that further delineate the exact nature of the exstrophied bladder in the newborn. One of the first papers to characterize the neuromuscular function of the bladder was published by [Shapiro and colleagues \(1985\)](#). In their work, muscarinic cholinergic receptor density and binding affinity were measured in control subjects and in patients with CBE. The

density of the muscarinic cholinergic receptors in both the control and exstrophy groups were similar, as was the binding affinity of the muscarinic receptor. Therefore, the neurophysiologic composition of the exstrophied bladder is not grossly altered during its anomalous development. Studies have investigated both the neural innervation of the newborn exstrophy bladder and its muscle and collagen content. [Lee and coworkers \(1996\)](#) looked at bladder biopsy specimens obtained from 12 newborns with bladder exstrophy, compared them with age-matched controls, and found an increase in the ratio of collagen to smooth muscle. Using anticollagen antibodies, they evaluated various types of collagen in these bladders and found there was no statistical difference in the amount of type I collagen in the bladders of newborns with exstrophy at initial closure, but there was a threefold increase in type III collagen. [Peppas and associates \(1999\)](#) found, in patients who gained adequate bladder capacities and were awaiting bladder neck reconstruction, that the ratio of collagen to smooth muscle decreased markedly after a successful closure and infection-free follow-up. [Lais and coworkers \(1996\)](#) reported similar findings and found that the ratio of smooth muscle to collagen increased after a successful closure.

In an extension of the studies just cited, [Mathews and coworkers \(1999b\)](#) looked at the number of myelinated nerves per field in the bladders of normal newborn subjects and those with exstrophy. The average number of myelinated nerves per field was significantly reduced in the exstrophy bladders compared with controls. This reduction in nerve fibers appears to be the result of a lack of small fibers with preservation of larger nerve fibers. In light of the findings, it is believed that bladder exstrophy in a newborn represents an earlier stage of bladder development and differentiation.

In a large study by [Rosch and colleagues \(1997\)](#), multiple immunocytochemical and histochemical markers were examined in patients with epispiadias or CBE. These studies involved indirect immunocytochemistry for vasoactive intestinal polypeptide (VIP), neuropeptide Y (NPY), substance P (SP), calcitonin gene-related peptide (CGRP), protein gene product (PGP) 9.5, and nicotinamide adenine dinucleotide phosphate diaphorase (NADPHd). No evidence of bladder muscle dysinnervation was found morphologically in any cases of CBE. Therefore, although a newborn with bladder exstrophy may have a maturational delay in bladder development, these bladders have the potential for normal development after a successful initial closure.

When the bladder is small, fibrosed, inelastic, and covered with polyps, functional repair may be impossible (Fig. 139-10). [Novak and colleagues \(2005\)](#) investigated the pathology and malignant potential of the polyps found in these small bladders. Two types of polyps were observed, with some overlap in findings: fibrotic and edematous. Both were associated with overlying squamous metaplasia in approximately 50% of cases. Varying degrees of von Brunn nests, cystitis cystica, and cystitis glandularis were noted. Cystitis glandularis was noted in a higher percentage of secondary closures. Because of the potential risk of adenocarcinoma associated with cystitis glandularis, future surveillance of these patients with urine cytology and cystoscopy as they enter adulthood is recommended. The more normal bladder may be invaginated or it may bulge through a small fascial defect, indicating the potential for satisfactory capacity after successful initial closure. **Not until examination under anesthesia can the true defect be adequately evaluated because the depth of this bladder extension into the pelvis cannot be appreciated unless the patient is under anesthesia.**

Bladder function was assessed in a group of continent exstrophy patients with normal reflexive bladders. Normal cystometrograms were obtained in 70% to 90% of patients ([Toguri et al, 1987](#)). [Diamond and associates \(1999\)](#), looking at 30 patients with bladder exstrophy at various stages of reconstruction, found that 80% of patients had compliant and stable bladders before bladder neck reconstruction. After bladder neck reconstruction, approximately half of the patients maintained normal bladder compliance and a lesser number maintained normal stability. The authors believed that compliance and stability were impaired after bladder neck reconstruction and that 25% of patients with exstrophy may

Figure 139-10. A, Small bladder template covered with polyps; unsuitable for closure. B, Extremely small bladder template in newborn; unsuitable for closure.

Figure 139-11. Ultrastructural changes noted in the exstrophic bladder. A, Normal muscle and nerve profiles in the newborn bladder. B, After failure of prior closure, significant deterioration is noted with increased intercellular collagen and degenerating muscle in an immunohistologic study. (From Mathews R, Gosling JA, Gearhart JP. Ultrastructure of the bladder in classic exstrophy: correlation with development of continence. *J Urol* 2004;172:1446–9.)

maintain normal detrusor function after reconstruction. In an earlier paper by [Hollowell and colleagues \(1993\)](#), 13 of 21 children revealed involuntary contractions and only 4 revealed stable bladders before bladder neck reconstruction. Also, 7 of 21 had increased pressures (greater than 10 cm H₂O), suggesting decreased compliance. The difference in findings between these two urodynamic studies is difficult to explain from an experimental perspective. However, standardized methods of bladder neck repair do not exist, and these differences may be reflected in the different urodynamic findings after bladder neck repair in these two groups of patients.

Several interesting aspects of the microstructure of the bladder in children with bladder exstrophy were noted by [Mathews and coauthors \(2004\)](#), who used specimens obtained from children with bladder exstrophy at various stages of reconstruction (newborn

bladder closure, bladder neck reconstruction, augmentation cystoplasty). At the cellular level, important differences were noted. Caveolae, which are important intracellular structures involved in cell-cell signaling, were found to be normal in the patients with a successful closure and improvement in bladder capacity and significantly lacking in the patients who required eventual augmentation cystoplasty ([Fig. 139-11](#)). In addition, the ultrastructure of cells in the patients in whom closure failed was noted to be abnormal. In a recent study by [Suson and colleagues \(2012\)](#) an attempt was made to further identify similarities and differences between exstrophy smooth muscle and normal bladder muscle. More than 95% of exstrophy and control smooth muscle cells stained positive for actin and myosin. Intracellular calcium concentration was lower in exstrophy smooth muscle than controls. More exstrophy cells migrated than control cells, although

it is not known if this movement is organized or directional. There were no differences in cell proliferation between the two groups. In a second study, [Suson and colleagues \(2012\)](#) showed that enhanced exstrophy smooth muscle cell migration was a result of excess transforming growth factor- β 1 signaling but was independent of increases in intracellular calcium concentration.

The upper urinary tract is usually normal, but anomalous development does occur. In a recent report by [Stec and colleagues \(2012a\)](#), 674 patients were reviewed; 462 were found to have had ultrasound examination. In this large review, 13 of 462 (2.8%) had a renal anomaly. The most common malformation was a duplicated collecting system (6); others included hypoplastic or absent kidney (3), pelvic kidney (2), ureteropelvic junction obstruction (1), and multicystic dysplastic kidney. This is a higher incidence than the 0.57% seen after 2 to 4 years of follow-up by antenatal screening ([Rosen-dahl, 1990](#)). The ureters have an abnormal course in their termination. The peritoneal pouch of Douglas between the bladder and the rectum is enlarged and unusually deep, forcing the ureter down laterally in its course across the true pelvis. The distal segment of the ureter approaches the bladder from a point inferior and lateral to the orifice, and it enters the bladder with little or no obliquity. Therefore, reflux in the closed exstrophy bladder occurs in 100% of patients, and reimplantation surgery is required at bladder neck reconstruction. If excessive outlet resistance is gained at the time of either initial closure or combined epispadias and bladder exstrophy closure, and recurrent infections are a problem even with suppressive antibiotics, ureteral reimplantation or Deflux injections are required before bladder neck reconstruction.

Exstrophy Complex and Variant

In addition to the three main presentations of the bladder exstrophy-epispadias complex—CBE, cloacal exstrophy, epispadias—many variations in anatomy and types of defects have been noted. Because there is probably a common embryologic origin for all of these defects, they all share many or some of the defects noted in the three major components of the complex—skeletal, urinary, and genital. The presence of a characteristic musculoskeletal defect of the exstrophy anomaly with no major defect in the urinary tract has been named *pseudoexstrophy* ([Marshall and Muecke, 1968](#)). Predominant characteristics include an elongated, low-set umbilicus and divergent rectus muscles that attach to the separated pubic bones. In this variant, the mesodermal migration has been interrupted in its superior aspect only, thus wedging apart the musculoskeletal elements of the lower abdominal wall without obstructing the formation of the genital tubercle.

In the superior vesical fissure variant of the exstrophy complex, the musculature and skeletal defects are exactly the same as those in classic exstrophy; however, the persistent cloacal membrane ruptures only at the uppermost portion, and a superior vesical fistula results that actually resembles a vesicostomy. Bladder extrusion is minimal and is present only over the normal umbilicus (see [Fig. 139-1B](#)).

In a large review of an exstrophy database of over 815 patients, [Lowentritt and colleagues \(2005\)](#) reported 25 exstrophy complex variants, of which six were cloacal exstrophy variants. Continence rates after bladder neck repair were compatible with classic exstrophy. Three cases were reported by [Arap and Giron \(1986\)](#) in which the patients had classic musculoskeletal defects, and two of the three were continent. Of the two male patients, one had an associated complete epispadias and the other had a completely normal penis. Therefore the external genital manifestations in exstrophy variants can be quite variable.

In addition to pseudoexstrophy, superior vesical fissure, and duplicated exstrophy, isolated occurrences of a fourth entity, covered exstrophy, have been reported ([Cerniglia et al, 1989](#)). This has also been referred to as *split symphysis variant*. A common factor in these patients is the presence of musculoskeletal defect associated with classic exstrophy but no significant defect of the urinary tract. [Chandra and associates \(1999\)](#) reported a covered exstrophy with incomplete duplication of the bladder. However, in cases of covered

Figure 139-12. Skin-covered exstrophy in a female patient. Note urethral sound in the bladder and the subcutaneous position below the skin of the abdominal wall. No bowel is sequestered on the abdominal wall, as has been reported in some patients with this variant.

exstrophy ([Narasimharao et al, 1985](#); [Cerniglia et al, 1989](#)), there has been an isolated ectopic bowel segment present on the inferior abdominal wall near the genital area, which can be either colon or ileum with no connection with the underlying gastrointestinal tract and only epispadias in the male. A patient seen at our institution had the standard appearance of most split symphysis variants, and one could actually see the bladder through a thin membrane of lower abdominal skin ([Fig. 139-12](#)); all of the classic musculoskeletal defects of exstrophy were present. These patients should all undergo formal exstrophy closure at birth.

There are two different forms of bladder duplication: anteroposterior duplication and side-by-side duplication. The former form is considered a duplicate exstrophy with a patch of everted bladder mucosa on the anterior abdominal wall and a second bladder lying in the pelvis. The ureters attach to the closed bladder, rendering the superficial mucosa dry ([Fig. 139-13](#)). The mainstay of treatment has been resection of the ectopic mucosa and closure of the abdominal wall defect. The other form of duplication involves patients who have two separately formed bladder halves in a left-right orientation with a midline septum between the bladders containing muscle. Each bladder has its own ureter and an intact sphincter. Often there is diastasis of the pubis and rectus muscle.

The bladder exstrophy-epispadias-cloacal exstrophy complex has a wide range of presentations. Variants are rare, but it is important to recognize the different appearances at birth, because the initial treatment will greatly influence the long-term outcome. Two patient groups had better outcomes than those with classic presentations—superior vesical fissure and skin-covered cloacal exstrophy. Because the sphincter is intact, patients with superior vesical fissure went through regular toilet training and became continent without the need for a later bladder neck procedure. Many reports of exstrophy variants include these patients, leading to the wrong belief that all patients with variants perform better than those with bladder exstrophy. [Lowentritt and colleagues \(2005\)](#) suggest that other than superior vesical fissure, all variants should be managed with formal exstrophy closure at birth and followed in the same manner as their classic presentations.

Prenatal Diagnosis

Even with modern ultrasound modalities, the prenatal diagnosis of bladder exstrophy is often difficult to delineate. Frequently, a

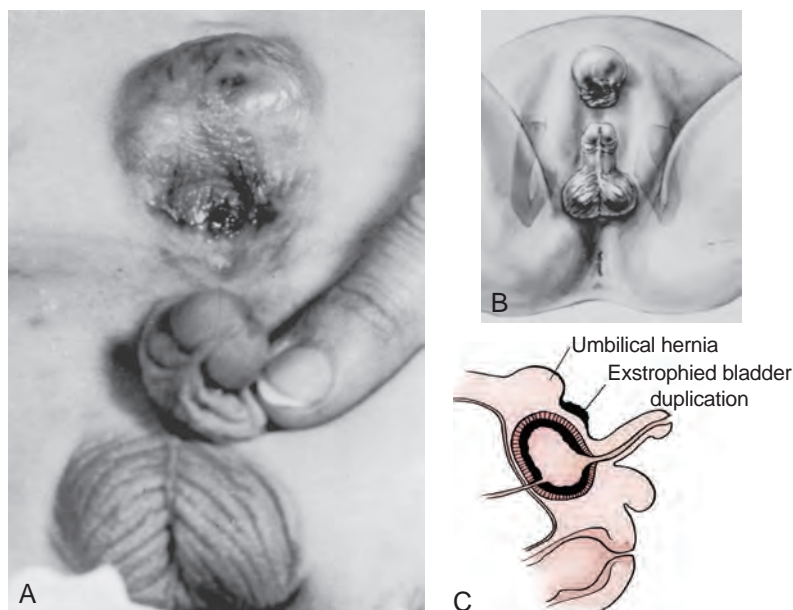

Figure 139-13. A-C, Duplicate exstrophy in a boy with an intact lower urinary tract.

diagnosis of omphalocele or gastroschisis is made and the exstrophy condition is overlooked. Ultrasound evaluation of the fetus by means of high-resolution real-time units allows a thorough survey of the fetal anatomy, even during routine obstetric ultrasound examinations (Gearhart et al, 1995a). Several groups have outlined important criteria for the diagnosis of CBE prenatally. In these reviews, the absence of a normal fluid-filled bladder on repeated examinations suggested the diagnosis, as did a mass of echogenic tissue on the lower abdominal wall (Mirk et al, 1986; Verco et al, 1986). In a review of 25 prenatal ultrasound examinations with the subsequent birth of a newborn with CBE, Gearhart and colleagues (1995a) made several observations: (1) absence of bladder filling, (2) a low-set umbilicus, (3) widening pubis ramus, (4) diminutive genitalia, and (5) a lower abdominal mass that increased in size as the pregnancy progressed and as the intra-abdominal viscera increased in size (Fig. 139-14).

The application of 3D ultrasonography and fetal MRI has only somewhat improved the antenatal diagnosis of bladder and cloacal exstrophy, because only 25% of cases of bladder exstrophy-epispadias complex are diagnosed prenatally (Goyal et al, 2012). In our practice, fetal MRI is reserved for patients in whom 3D ultrasonography is not sufficient to differentiate satisfactorily between classic and cloacal exstrophy, or when other severe anomalies are suspected. The main reason for the prenatal diagnosis of bladder exstrophy is so that the parents can be counseled regarding the risks and benefits and other aspects of the condition. After appropriate counseling, arrangements can be made for delivery of the baby in a specialized exstrophy center where immediate reconstruction of the exstrophy can occur. Delivery in a specialized exstrophy center allows the parents to be exposed to the expertise of multiple disciplines, including the all-important psychological support these parents need when a child with a birth defect of this magnitude is delivered.

SURGICAL RECONSTRUCTION OF BLADDER EXSTROPHY

Sweetser and associates (1952) initially described a staged surgical approach for bladder exstrophy. Four to 6 days before bladder closure, bilateral iliac osteotomies were performed. Epispadias repair was performed as a separate procedure. The continence procedure was limited to freeing the fibers from the intrasymphyseal band and wrapping this band around the urethra at the time of closure to increase outlet resistance.

Figure 139-14. Prenatal ultrasound scan demonstrating bladder exstrophy. A, Longitudinal view showing the low-set umbilicus (cyan arrow), lack of intra-abdominal bladder, and lower abdominal mass (red arrow). B, Transverse view through the plane (X) in A shows presence of the umbilicus (cyan arrow) and the upper edge of the bladder plate that appears hyperechoic (red arrow).

The initial staged approach to functional bladder closure included three separate stages: bladder and abdominal wall closure; bladder neck reconstruction and antireflux procedure; and later epispadias repair. This approach was recommended for most cases of exstrophy reconstruction beginning in the early 1970s (Cendron, 1971; Jeffs et al, 1972; Williams and Keaton, 1973). Although this procedure was successful, it has been modernized in the last 15 years to include bladder closure, abdominal wall closure, and posterior urethral closure well onto the penis in the newborn period with bilateral innominate and vertical iliac osteotomy, if indicated; epispadias repair at 6 months to 1 year of age; and bladder neck reconstruction along with antireflux procedure at age 4 to 5 years, when the child has achieved an adequate bladder capacity for bladder neck reconstruction and is motivated to participate in a postoperative voiding program (Gearhart and Jeffs, 1998).

Other methods of treatment of the newborn with bladder exstrophy have been offered. Grady and Mitchell (1999) proposed combining bladder exstrophy closure with penile repair in the newborn period. Baka-Jakubiak (2000) recommended newborn exstrophy closure alone and combined bladder neck reconstruction and epispadias repair when the child reaches a satisfactory age for participation in a voiding program. Kelly (1995) has recommended a staged repair in which no osteotomy is used and a second-stage “radical soft-tissue mobilization” is performed before later urethral repair. Schrott and colleagues (1984) recommended bladder closure, ureteral reimplantation, epispadias repair, and bladder neck reconstruction in the newborn period. Lastly, Stein and coworkers (1999) recommended ureterosigmoidostomy in the newborn period with abdominal wall and bladder closure.

Evaluation and Management at Birth

At birth, although the bladder mucosa is usually smooth, pink, and intact, it is also sensitive and easily denuded. In the delivery room the umbilical cord should be tied with 2-0 silk close to the abdominal wall so that the umbilical clamp does not traumatize the delicate mucosa and cause excoriation of the bladder surface. The bladder can then be covered with a nonadherent film of plastic wrap (e.g., Saran Wrap) (Fig. 139-15) to prevent sticking of the bladder mucosa to clothing or diapers. In addition, each time the diaper is changed the wrap should be removed, the entire bladder surface irrigated with sterile saline, and clean wrap placed over the bladder surface area.

The parents typically need reassurance at this stage. Counseling of the parents and decisions regarding eventual therapy should begin prenatally if the condition is diagnosed by prenatal ultrasonography. The parents should be educated by a surgeon with a

special interest and experience in managing the exstrophy spectrum. An exstrophy support team should be available and should include a pediatric orthopedic surgeon, pediatric anesthesiologist, social workers, nurses with special interest in bladder exstrophy, and a child psychiatrist or psychologist with expertise and experience in genital anomalies. The Association for the Bladder Exstrophy Community is available and has a website for parents and family members to obtain further information about the bladder exstrophy condition.

Cardiopulmonary and general physical assessment measures can be carried out in the first few hours of life. Well-done ultrasound studies are usually sufficient to provide evidence of renal structure, function, and drainage, even in the first few hours of life before the patient undergoes closure of the exstrophy defect.

Circumstances may be less than ideal at birth. A thorough neonatal assessment may have to be deferred until transportation to a major children's medical center can be arranged. In these days of modern transportation, no child is ever more than a few hours away from a neonatal center with full diagnostic and consultative services. During travel the bladder should be protected by a plastic membrane, as in the nursery, to prevent damage to the delicate newborn bladder mucosa.

Selection of Patients for Immediate Closure

Successful treatment of exstrophy with functional closure demands that the potential for success in each child be carefully considered at birth by an experienced exstrophy surgeon. The size and the functional capacity of the detrusor muscle are important considerations for the eventual success of functional closure. Correlation between apparent bladder size and the potential bladder capacity must not be confused. In minor grades of exstrophy that approach the condition of complete epispadias with incontinence, the bladder may be small yet may demonstrate acceptable capacity, either by bulging when the baby cries or by indenting easily when touched by a sterile gloved finger in the operating room with the child under anesthesia. **Sometimes a good bit of previously unappreciated bladder can be discovered behind the fascia on examination with anesthesia** (Gearhart and Jeffs, 1998). Once the bladder is relieved of surface irritation and repeated trauma, the small bladder can enlarge and increase in capacity with the absence of sphincter activity and with minimal outlet resistance.

Small Exstrophy Bladder Unsuitable for Newborn Closure

A small, fibrotic bladder patch that is stretched between the edges of the small triangular fascial defect without elasticity or contractility cannot be selected for the usual closure procedure (Gearhart and Jeffs, 1998) (see Fig. 139-10A). Examination with the patient under anesthesia is often required to assess the bladder adequately, particularly if considerable edema, excoriation, and polyp formation have developed between birth and the time of assessment. **Decisions regarding the suitability of bladder closure or the need for waiting should be made only by surgeons with a great deal of experience in the exstrophy condition** (Gearhart and Jeffs, 1998). Some conditions preclude primary closure, including penoscrotal duplication, ectopic bowel within the extruded bladder (a relative contraindication), a hypoplastic bladder, and significant bilateral hydronephrosis.

In a paper submitted by Lakshmanan and colleagues (2008) of an exstrophy database of 1248 classic exstrophies, it was found on initial judgment that the bladder was too small for closure in 46 patients evaluated at birth. There were 36 boys and 10 girls who underwent delayed closure at a mean age of 13.2 months. Osteotomy was performed on 41 (89%). All had a successful delayed primary closure. Eighteen boys had a simultaneous epispadias repair. Sixty-one percent developed sufficient capacity for bladder neck reconstruction, and 39% are continent. Compared with data by Novak and colleagues (2010), these rates are more than double the continence rates seen in bladder neck repair after failed primary closure and successful secondary closure.

Figure 139-15. Use of plastic wrap to keep bladder plate moist before closure.

Thus, waiting for the bladder template to grow for 6 to 12 months in the child with a small bladder is not as risky as submitting a small bladder template to closure in an inappropriate setting, resulting in dehiscence and possible future incontinence. If the bladder does not grow to sufficient size for closure after 6 to 12 months, other options include excision of the bladder and a non-refluxing colon conduit or ureterosigmoidostomy.

Osteotomy

Children born with bladder exstrophy have not only an exposed bladder but a wide diastasis of the pubic rami (average 4.8 cm), resulting in an open pelvic ring. In addition, the larger the bladder template, the wider the resultant diastasis and the greater the need for osteotomy. The musculoskeletal function of the hip and lower extremity appears to be normal throughout childhood; however, the gait is characterized by external foot rotation, which lessens with growth as lower extremity muscle function strengthens, even if osteotomy is not performed.

Several types of pelvic osteotomies have been developed to help to close the pelvic ring, decrease the stress on the abdominal wall during initial exstrophy closure, and improve the outcome of future genitourinary reconstruction. Shultz (1958) was the first, as far as we know, to describe bilateral posterior iliac osteotomy as part of a two-stage repair of bladder exstrophy. Bilateral posterior iliac osteotomy was performed, and 1 to 3 weeks later exstrophy closure was accomplished. This early osteotomy was shown to lower rates of wound dehiscence and to help achieve a more secure and better genitourinary reconstruction.

Patients may undergo pelvic osteotomy at any stage of exstrophy repair if the diastasis prevents attainment of these urologic goals. **In general, we do not routinely perform osteotomy on newborns unless the diastasis is over 4 cm or the malleability of the pelvis is poor.** The laxity of the sacroiliac ligaments usually allows closure of the defect without undue tension in the first 48 to 72 hours of age. We make this decision with the patient under anesthesia at the time of primary closure with our pediatric orthopedic colleagues.

Types of osteotomies that have been used include bilateral osteotomy of the superior pubic ramus, diagonal osteotomy of the iliac wing, and anterior innominate osteotomy with or without vertical iliac osteotomy. The more commonly used combined anterior innominate and vertical osteotomy was developed for several reasons: (1) the osteotomy is performed with the patient in the supine position as for the urologic repair, avoiding the need to turn the patient; (2) the anterior osteotomy also allows placement of an external fixator and intrafragmentary pins under direct vision; (3) a greenstick-type closing-wedge osteotomy of the ilium is also performed adjacent to the sacrum in most patients, creating two large bony fragments that are easily movable; (4) the cosmetic appearance of this osteotomy is superior to that of a posterior iliac osteotomy (Gearhart et al, 1996b); and (5) the superior pelvic bone malleability and ease of apposition of the pubic bone without tension.

After failure of initial closure in children with significant pubic diastasis, as seen in large bladder templates and cloacal exstrophy, osteotomy is always required. Pubic approximation may not be possible in a single step at the time of abdominal closure when the diastasis is extreme (>6 cm). The use of staged closure of the pelvis after osteotomy has been used successfully in this circumstance. This technique has been used for the treatment of children with extreme diastasis, even in younger patients, and the cloacal exstrophy condition.

Pelvic osteotomy performed at the time of initial closure confers several advantages, including (1) easy approximation of the symphysis with diminished tension on the abdominal wall closure and elimination of the need for fascial flaps; (2) placement of the posterior vesicourethral unit deep within the pelvic ring, enhancing bladder outlet resistance; and (3) bringing the large pelvic floor muscles near the midline, where they can support the bladder neck and aid in eventual urinary control

(Fig. 139-16). After pubic approximation with osteotomy, some patients show the ability to stop and start the urinary stream, experience dry intervals, and in some cases become completely continent (Gearhart and Jeffs, 1991a). In a review of a large number of patients referred to our institution after failed exstrophy procedures, it was found that a majority of the patients who had partial or complete dehiscence of the bladder or major bladder prolapse had not undergone an osteotomy at the time of initial bladder closure (Gearhart et al, 1993b). We recommend performing bilateral transverse innominate and vertical iliac osteotomy when bladder closure is performed after 72 hours of age (Fig. 139-17). In addition, if the pelvis is not malleable or if the pubic bones are more than 4 cm apart at the time of initial examination under anesthesia, osteotomy should be performed, even if closure is done before 72 hours of age. A well-coordinated surgery and anesthesia team can perform osteotomy and proceed to bladder closure without undue loss of blood or risk of prolonged anesthesia in the child. However, it must be realized that osteotomy together with posterior urethral and bladder closure and abdominal wall closure is a 5- to 7-hour procedure in these infants.

If the patient is younger than 72 hours and examination under anesthesia reveals that the pubic bones are malleable and able to be brought together easily in the midline by medial rotation of the greater trochanters, the patient can undergo closure without osteotomy. No chances should be taken with a decision of this magnitude, and if any doubt exists, an osteotomy should be performed.

The most frequently used osteotomy today is the bilateral anterior innominate and vertical iliac osteotomy, popularized by Gearhart and colleagues in 1996 (Gearhart et al, 1996b). This approach improves the ease of symphyseal approximation in the patient with exstrophy compared with posterior approaches. In our experience, this osteotomy is superior to the pubic mobilization seen with simple bilateral transverse anterior innominate osteotomy or even pubic ramotomy. **With the ease of approximation obtained with this combined osteotomy, tension on the midline abdominal closure is lessened and the rates of bladder dehiscence and bladder prolapse are markedly decreased (Gearhart and Jeffs, 1998).** In addition, pelvic closure allows anterior movement of the levator ani to strengthen the puborectalis sling. This helps position the bladder neck and posterior urethra deep within the pelvic ring and improved continence rates. This also moves the pelvic floor muscles into a more anterior position, thus providing more support for the anterior pelvic organs.

Combined osteotomy is performed by placing the patient in the supine position, preparing and draping the lower body below the costal margins, and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the iliac wings inferiorly to the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated, and a Gigli saw is used to create a transverse innominate osteotomy exiting anteriorly at a point halfway between the anterior superior and anterior inferior spines (see Fig. 139-17). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy to allow placement of external fixator pins in the distal segments. In addition to the transverse osteotomy, the posterior ilium may be incised from the anterior approach in an effort to correct the deformity more completely. For this part of the osteotomy, an osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joints. The proximal posterior iliac cortex is left intact and used as a hinge (see Fig. 139-17). This combination osteotomy easily corrects the abnormalities in both the anterior and posterior segments of the pelvis.

Two fixator pins are placed in the inferior osteotomized segment, and two are placed in the wing of the ilium superiorly. Radiographs are obtained to confirm pin placement, soft tissues are closed, and the urologic procedure is performed (see Fig. 139-16). At the end of the procedure, the pelvis is closed with a suture between the two pubic rami. The external fixators are then applied between the pins to hold the pelvis in a correct position. In a newborn with less than optimal amounts of cancellous bone, only one pin is placed

Figure 139-16. A, Eight-month-old patient with classic bladder exstrophy closed at birth without osteotomy with complete dehiscence. Patient was initially seen at 8 months of age. inferiorly and superiorly in the wing of the ileum, instead of two as in older children.

Radiographs are taken 7 to 10 days after surgery to look for complete reduction of the symphyseal diastasis. If this diastasis has not been completely reduced, the right and left sides can be gradually approximated by means of the fixator bars over several days. Longitudinal skin traction is used to keep the legs still (Fig. 139-18). The patient remains supine in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for 4 to 6 weeks, until adequate callus is seen at the site of the osteotomy (see Figs. 139-16B and 139-17). Postoperatively, in newborns who undergo closure without osteotomy in the first 48 to 72 hours of life, the baby is immobilized in modified Bryant traction in a position in which the hips have 90 degrees of flexion. When modified Bryant traction is used, the traction is used for 4 weeks. A horizontal mattress suture of No. 2 nylon is placed between the fibrous cartilage of the pubic rami and tied anteriorly to the pubic closure at the time of bladder closure. Evidence obtained by [Sussman and associates \(1997\)](#) from biomechanical testing in an intact piglet pelvic model revealed that all methods of pubic approximation were weak compared with the intact symphysis. However, the best technique with the strongest load-to-failure ratio was a No. 2 nylon horizontal mattress suture.

Complications of Osteotomy and Immobilization Techniques

Complications of inadequate immobilization can include failure of the closure, bladder prolapse, loss of suprapubic tubes, and ureteral stents. Closely related to inadequate immobilization is inadequate pain and movement control. With tunneled epidural catheters for 2 to 3 weeks, pain and movement are well controlled while the pelvic bone callus formation increases in the osteotomy wound and the wound stabilizes.

Some centers still prefer to use spica casts and mummy wraps. In a series from Seattle, the authors preferred spica casts with or without osteotomy over other techniques and felt this allowed earlier discharge from the hospital ([Shnorhavorian et al, 2010](#)). However, in a large series of 86 failed exstrophy closures, [Meldrum and colleagues \(2003\)](#) found that most had been immobilized with a mummy wrap or spica cast. Successful closure was noted in 97% of those immobilized with an external fixator and modified Buck traction.

[Sponseller and colleagues \(2001\)](#) reported on a total of 86 combined bilateral anterior innominate and vertical iliac osteotomies performed in 88 children. Ten children had cloacal exstrophy and

72 bladder exstrophy with at least 2 years of clinical follow-up (mean 4.8 years). Complications included seven cases of transient left femoral nerve palsy, which resolved fully by 12 weeks after surgery. There were no cases of right femoral nerve palsy, although the same surgeon performed the same technique on both sides. Patients with transient femoral nerve palsy were on bed rest for the first 6 to 8 weeks; a knee immobilizer was needed for the remaining 6 weeks until resolution. Other complications included three cases of delayed ileal union, one case of superficial infection of the ileal femoral incision that required irrigation and debridement, one case of transient right thigh abductor weakness, one infection of the ileum around a pin site requiring irrigation and debridement, and one case of transient right peroneal palsy. Almost all patients had skin inflammation around the pins, particularly those in the proximal (iliac crest) segments. This was always controlled with the use of oral antibiotics. In a paper by [Satsuma and colleagues \(2006\)](#), comparisons were made between patients who underwent posterior iliac or combined osteotomy. Pubic approximation was better and the mean recurrence far less in the combined transverse innominate and vertical iliac osteotomy. Thus, the combined approach corrected and maintained the pelvic ring with fewer complications than a posterior pelvic osteotomy.

When good callus formation is seen on radiography, the fixating device and pins are removed at the bedside with the patient under light sedation. The age of the patient plays a role in the amount of correction of the diastasis that is maintained over time. On review of the previously described types of osteotomy, both classic and cloacal exstrophy patients gained approximation, although the former group gained greater correction toward normal ([Gearhart et al, 1996b](#)). Greater preoperative diastasis as well as less optimal bone density in the newborn contributes to the greater difficulty in obtaining and maintaining closure of the pelvic bone deformity over time.

It is our impression that partial recurrence of diastasis occurs in classic exstrophy by two mechanisms, even after osteotomy. First, the pelvis may partially derotate owing to early loosening of pins before the time of osteotomy healing; this is seen mostly in infants. In the older child, increased bone density allows more rigid external fixation and thus better maintenance of the corrected position. Second, there is long-term undergrowth of the ischiopubic segment, which has been shown to be 33% smaller than normal in the adult with exstrophy, as the pelvis grows. Pubic diastasis increases with growth in the patient with uncorrected exstrophy. Therefore, even with some loss of approximation, significant correction remains in comparison to the unoperated state. **We regard the main role of osteotomy to be relaxation of tension on the bladder, posterior urethra, and abdominal wall repair during healing.** Therefore, we

use osteotomy less in newborns and young infants because ligament laxity allows the pelvis to be closed without tension if the diastasis is reasonable and pubic bones are malleable. However, it becomes essential in the older child with a failed exstrophy repair, in the patient with cloacal exstrophy, and in a newborn with a wide diastasis and excellent bladder template. In patients undergoing combined exstrophy closure and epispiadias repair, osteotomy allows the pubis to be joined, making it easier for the corpora to be brought over the closed proximal urethra (Gearhart et al, 1998). In a large series of failed exstrophy reclosures (mean age 23.2 months), 56 patients were found who underwent repeat pelvic osteotomy (Nelson et al, 2006). All of the reclosures were successful, and 95% of the patients had a normal gait after reoperative osteotomy. There were no femoral or sciatic nerve palsies, and only five local pin site infections, which were easily treated. Repeat pelvic osteotomy is safe with low complications in experienced hands.

Whichever type of osteotomy is used, pelvic ring closure not only allows midline approximation of the abdominal wall structures but also allows the levator ani and puborectalis muscles to lend potential support to the bladder outlet, thus increasing resistance to urinary outflow (see Fig. 139-16D) (Sponseller et al, 1991; Gearhart et al, 1993b, 1996b; Schmidt et al, 1993; McKenna et al, 1994). Furthermore, a continence procedure can be performed later on the bladder neck and urethra deep within the closed pelvic ring at a distance from the surface without independent movement of the two halves of the pubis. The urethra and bladder neck are set more deeply in the true pelvis, in a more normal relationship than when acutely angulated.

Surgical Options in the Newborn with Classic Bladder Exstrophy

Although modern staged repair of exstrophy (MSRE) currently enjoys widespread popularity, other methods have been described for the primary reconstruction of exstrophy and are used in good centers. This section discusses the other types of repair and their use and application. The outcomes and complications are discussed in separate sections, as many are similar and their correction the same.

Warsaw Approach

First described by Baka-Jakubiak in 2000, the Warsaw procedure involves closing the bladder, posterior urethra, pubis, and abdominal wall at the time of primary closure with or without osteotomy but always with appropriate immobilization. Osteotomy is used in all patients older than 72 hours or in any with a diastasis greater than 5 cm. A spica cast is used for 3 weeks and an elastic bandage for 3 additional weeks. When the bladder has achieved suitable capacity (more than 70 mL) and the child is interested in continence, bladder neck repair is performed along with epispiadias repair. Baka-Jakubiak used this approach in over 100 patients with classic exstrophy and complete epispiadias. The intersymphyseal band is routinely divided to allow better visualization of the bladder neck and posterior urethra region. An additional proposed benefit of this procedure is that the bladder neck and posterior urethral unit is straighter at the second procedure, and this allows easier catheterization and cystoscopy after reconstruction. A 10% complication rate, mainly urethral fistula or stricture, is noted with this procedure.

Kelly Repair

The radical soft-tissue mobilization procedure was developed by Kelly in the late 1980s and early 1990s as a means to improve on the technique described by Ansell (1983) and to obviate pelvic osteotomies that were often required to obtain a tension-free closure. It is a multistage repair that includes (1) closure of the bladder dome and hernia repair at birth, followed at age 3 to 6 months by (2) reconstruction of the proximal urethra with

associated sphincteric tissue with penile lengthening and creation of a penoscrotal urethroostomy in boys, and (3) repair of the resulting penoscrotal hypospiadias at around 3 years of age. The unique aspects relate to the second stage, in which a more radical mobilization of the pelvic floor muscles is performed. Specifically, the dissection includes the periosteum of the ischium and pubis where one encounters the attachment of the voluntary and involuntary sphincter muscles, as well as the pudendal nerves and vessels. The muscles are then wrapped around the reconstructed proximal urethra in an attempt to provide a continence mechanism. The neourethra itself is constructed from the urethral plate on the dorsum of the penis after it is dissected from the corporeal bodies much as in the penile disassembly technique. However, unlike the penile disassembly technique, the meatus is always brought to the penoscrotal junction and later is brought distally.

Complete Repair

Developed by Mitchell, the complete repair combines the standard bladder closure with the “penile disassembly” technique for epispiadias repair in an effort to decrease the number of procedures required for reconstruction and potentially provide continence without the need for formal bladder neck reconstruction (Grady and Mitchell, 1999).

This technique of penile repair was developed by Mitchell and Bägli (1996). It has now been incorporated in the complete primary repair of exstrophy (CPRE) for primary closure in the newborn.

The penis is dissected into three components—the right and left corpora with their associated hemiglans and the urethral wedge (urethral plate with its associated spongiosa) (Fig. 139-19). The dissection as in the Cantwell-Ransley repair begins on the ventral aspect of the penis. The dissection moves medially just above the Buck fascia but is taken down to the tunica albuginea of the corpora. Care is taken to preserve the spongiosum with the urethral wedge, and this dissection is carried posteriorly to the area of the bladder neck. The penis is then separated into the three aforementioned components. Several authors have found problems getting the reconstructed urethra back to the tip of the glans and have recommended interrupted suturing of the urethral plate or leaving the most distal part of the urethral plate attached to the glans as in the Cantwell-Ransley repair. Others have found the need to make the patients hypospiadiac and then perform a later hypospiadias repair because of a shortened urethral plate. The rate of hypospiadias created has been reported to be from 30% to 70% of cases. If the urethra can be brought up to each hemiglans, an orthotopic meatus is configured. The glans is brought together using interrupted mattress sutures of polydioxanone suture (PDS) followed by horizontal mattress sutures of 7-0 nonfilament suture to bring the glanular epithelium together. The urethra is matured to the glans with interrupted sutures of 7-0 braided polyglactin sutures. The corpora are then brought over the reconstructed urethra with interrupted sutures. Skin closure is similar to that of standard hypospiadias repair with fine absorbable sutures. If concomitant exstrophy closure is to be done, the dissection then moves proximally into the pelvis to be able to move the structures into the pelvis. Another part of the complete repair is bladder neck “tailoring” to provide some outlet resistance after closure in the newborn (see Fig. 139-19).

Mitchell emphasizes the importance of dissecting the perineal membrane from the pubis, allowing the bladder and posterior urethra to be set deep into the pelvis. This feature is common to all properly performed exstrophy reconstructions and helps ensure success. The dissection of the urethral plate from the corpora leaves 60% to 75% of patients with hypospiadias (Hafez and El-Sherbiny, 2005), and 50% of children require urethral reimplantation in the first year of life (Grady and Mitchell, 1999).

Mainz Repair

Hohenfelner and colleagues first began using ureterosigmoidostomy for both failed exstrophy patients and for patients with small

Figure 139-19. A, Initial cystogram under anesthesia showing small bladder capacity after bladder closure. B, Improvement in bladder capacity noted after urethroplasty.

bladder templates, which led to its use as a technique in primary exstrophy closures. Beginning in 1964, this was begun in all newborns with exstrophy, irrespective of bladder template size at birth. At the age of 2, the patient undergoes ureterosigmoidostomy. Some of the remnant bladder is made into a small seminal receptaculum and the penis is reconstructed during the same procedure. In girls, the external genitalia are reconstructed and anterior fixation of the uterus is performed. In both boys and girls, cosmetic correction is usually needed later. However, this usually means only one further operation. In 1996, Fisch and colleagues reported long-term results with the Mainz Sigma pouch (Fisch et al, 1996). This was designed to reduce intracolonic pressures and to maintain better fecal continence. Most of the patients are immediately started on oral alkalinization.

Erlangen Approach

The Erlangen approach is clearly the most evolved of any of the primary closure techniques. In the Erlangen approach, developed by Schrott and popularized by Rosch, if the bladder template is deemed of adequate size, the "total" repair is done at 8 weeks of age. If the template is too small at birth, the bladder only is closed with bilateral groin exploration, closure of the pubis, epispadias repair, and no osteotomy. In the classic Erlangen total repair, the bladder is closed along with bilateral reimplantations, bladder neck plasty, bilateral groin exploration, epispadias repair, pubic closure, no osteotomy, and an epidural catheter for 5 days. Osteotomy is only done in cloacal exstrophy and reoperative closures. Thus, the Erlangen repair is truly a complete repair, encompassing all phases of exstrophy repair in one setting (Schrott et al, 1984).

Regardless of the method of exstrophy reconstruction chosen for the newborn, certain surgical principles remain: (1) radical mobilization of the posterior vesicourethral unit from surrounding tissue; (2) combined closure with epispadias repair in only carefully selected patients; (3) tension-free closure of the abdominal

wall and pelvic bones with adjunctive osteotomy if needed; and (4) definition of strict criteria for selection of newborns to undergo closure.

Modern Reconstruction of Bladder Exstrophy

The primary objective in functional closure is to convert the bladder exstrophy into a complete epispadias with the urethra well up onto the proximal shaft or midshaft of the penis with combined complete epispadias repair in only highly select patients. The resultant incontinence with balanced posterior outlet resistance not only preserves renal function but also stimulates bladder growth. Typically, epispadias repair is now performed at around 6 months of age, after testosterone stimulation. Bladder neck repair usually occurs when the child is 4 to 5 years of age, has an adequate bladder capacity, and, most important, is ready to participate in a postoperative voiding program. Many repairs such as the Erlangen, Kelly, and CPRE were purported to establish continence without the need for bladder neck repair, but recent reports have shown the need for an outlet procedure in almost all patients (Gearhart et al, 2005, 2007; Shoukry et al, 2009; Gargollo et al, 2011).

Bladder, Posterior Urethral, and Abdominal Wall Closure

Various steps in primary bladder closure are illustrated in Figure 139-20A to H. A strip of mucosa 2 cm wide, extending from the distal trigone to well below the verumontanum in the male and to the level of the vaginal orifice in the female, is outlined for prostatic and posterior urethral reconstruction in the male and adequate urethral closure in the female. The male urethral groove may be adequate, in which case no transverse incision of the urethral plate need be performed for urethral lengthening (Fig. 139-20A). We tend not to incise a urethral plate unless the length of the urethral groove from the verumontanum to the urethral glans is so short that it interferes with eventual penile length and produces dorsal

Figure 139-20. Steps in the initial closure of the bladder and posterior urethra with or without osteotomy. The bladder plate is dissected off the anterior abdominal wall. angulation. If so, the urethral groove is lengthened after the manner of Johnston (1974) or Duckett (1977). The drawings in Figure 139-20B and C show marking of the incision just above the umbilicus, down the junction of the bladder and paraexstrophy skin, to the level of the urethral plate.

An appropriate plane is entered just above the umbilicus, and a plane is established between the rectus fascia and the bladder (Fig. 139-20D). The umbilical vessels are doubly ligated and incised and allowed to fall into the pelvis. The peritoneum is taken off the dome of the bladder at this point so that the bladder can be placed deep into the pelvis at the time of closure. The plane is continued caudally down between the bladder and rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. The pubis is encountered at this junction, and a double-pronged skin hook can be inserted into the bone at this time and pulled laterally to accentuate the urogenital diaphragm fibers and help the surgeon radically incise these fibers between the bladder neck, posterior urethra, and pubic bone (Fig. 139-20E). Gentle traction on the glans at this point shows the insertion of the corporeal body on the lateral inferior aspect of the pubis. These urogenital diaphragm fibers are taken down sharply with electrocautery down to the levator hiatus in the pelvic floor in their entirety (Fig. 139-20F). If this maneuver is not performed adequately, the posterior urethra and bladder will not be placed deeply into the pelvis, and when the pubic bones are brought together, the posterior vesicourethral unit will be brought anteriorly into an unsatisfactory position for later Cantwell-Ransley epispadias repair. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate to create as much additional urethral and penile length as possible. Further urethral lengthening can be performed at the time of epispadias repair.

Penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments on the anterior part of the inferior pubic rami. However, because Silver and colleagues (1997b) showed that there is a 50% shortage of length of the corporeal bodies in exstrophy versus normal controls, any penile length that is obtained is through correction of chordee and change in angulation of the penis rather than true penile lengthening. The wide band of fibers and muscular tissue representing the urogenital diaphragm is detached subperiosteally from the pubis bilaterally (Fig. 139-20E). Reluctance to free the bladder neck and urethra well from the inferior ramus of the pubis moves the neobladder opening cephalad should any separation of the pubis occur during healing, thus increasing the chance of bladder prolapse. The mucosa and muscle of the bladder, bladder neck, and urethra are then closed well onto the penis in the midline anteriorly (Fig. 139-20G). This posterior vesicourethral unit should be tapered over a 12-Fr sound. The purpose of this tapering is to slightly narrow and elongate this unit to allow it to be placed deeply into the pelvis. The size of the opening should allow enough resistance to aid in bladder adaptation and to prevent prolapse but not enough outlet resistance to cause upper tract changes. The posterior urethra and bladder neck are buttressed with a second layer of local tissue if possible. The bladder is drained by a suprapubic nonlatex Malecot catheter for a period of 4 weeks. The urethra is not stented to avoid necrosis with accumulation of secretions in the neourethra. Stents provide drainage during the first 10 to 14 days after closure, because swelling caused by the pressure of closure of a small bladder can obstruct the ureters and give rise to obstruction and transient hypertension. If there are no problems with the stents during healing, we leave the stents in for as long as 2 to 3 weeks.

When the bladder and urethra have been closed and the drainage tubes placed, pressure over the greater trochanters bilaterally allows the pubic bones to be approximated easily in the midline. Horizontal mattress sutures are placed in the pubis and tied with a knot away from the neourethra (Fig. 139-20H). Often we are able to use another stitch of No. 2 nylon at the most caudal insertion of the rectus fascia onto the pubic bone. This maneuver adds to the security of the pubic closure. A V-shaped flap of abdominal skin at a

point corresponding to the normal position of the umbilicus is tacked down to the abdominal fascia, and a drainage tube exits this orifice. The method described by Hanna (1986) is our most commonly performed procedure. Before and during the procedure, the patient is given broad-spectrum antibiotics in an attempt to convert a contaminated field into a clean surgical wound.

In the very short penis at birth, the urethral groove must be transected. As described by Duckett (1977), the groove is then cut distal to the verumontanum with continuity maintained between the thin, mucosal, paraexstrophy non-hair-bearing skin adjacent to the posterior urethra and bladder neck and the skin and mucosa of the penile skin and glans. Flaps in the area of the thin skin are subsequently moved distally and rotated to reconstruct the urethral groove, resurfacing the penis dorsally. The corporeal bodies are not brought together at this juncture because later Cantwell-Ransley repair is planned.

Combined Bladder Closure and Epispadias Repair

MSRE has yielded consistently good cosmetic and functional results, and the use of osteotomy has improved the potential for successful initial closure and later continence. In an effort to decrease costs, decrease the morbidity associated with multiple operative procedures, and possibly affect continence, there has been interest in performing single-stage reconstruction or combining procedures in appropriately selected patients. This technique was first described by Lattimer and Smith (1966) but was abandoned in the 1970s because of high complication and failure rates. The technique was revisited by Gearhart and Jeffs (1991a) for failed exstrophy closures and more recently by Grady and Mitchell for newborn patients (1999). In the combined exstrophy and epispadias repair, bladder closure is combined with the modified Cantwell-Ransley epispadias repair (Gearhart and Mathews, 2000; Baird et al, 2005c). This technique can be applied to both delayed primary closure and failed closures. This method does not require making the patient hypospadiac.

Results have now emerged in groups of boys undergoing single-stage reconstruction (bladder closure and epispadias repair) in infancy (Gearhart et al, 1998; Baird et al, 2005c). In our opinion, this technique should be limited to boys of older age (older than 6 months) because of evidence indicating that potential complication of these combined procedures is significant loss of penile and corporeal tissue that makes further reconstruction problematic (Cervellione et al, 2010). Patients should be carefully selected, and use of these extensive procedures by the occasional exstrophy surgeon is not recommended. Selection should take into account phallic size and length, depth of the urethral groove, and size of the bladder template in those with delayed primary closures, as well as perivesical and urethral scarring in those who have undergone a prior failed closure (Gearhart and Jeffs, 1991a; Gearhart et al, 1998; Baird et al, 2005c).

Management after Primary Closure

The initial step of the MSRE converts a patient with exstrophy into one with penile shaft epispadias and incontinence. Before removal of the suprapubic tube, 4 weeks after surgery the bladder outlet is calibrated by a urethral catheter or a urethral sound to ensure free drainage. A complete ultrasound examination is performed to ascertain the status of the renal pelvis and ureters, and appropriate urinary antibiotics are administered because all patients have reflux after closure. Residual urine is estimated by clamping the suprapubic tube, and specimens for culture are obtained before the patient leaves the hospital and at subsequent intervals to detect infection and ensure that the bladder is empty. If the initial ultrasound examination shows good drainage, upper tract imaging by ultrasonography is repeated 3 months after discharge from the hospital and at intervals of 6 months to 1 year during the next 2 to 3 years to detect any upper tract changes caused by reflux, infection, or obstruction. Prophylactic antibiotics should be continuous because all patients with bladder exstrophy, once it has been closed,

have vesicoureteral reflux. If a useful continence interval has resulted from the initial closure, a further operation for incontinence may not be required; however, this situation is quite unusual. After the conversion from exstrophy to complete epispadias with incontinence, the bladder gradually increases in capacity as inflammatory changes in the mucosa resolve.

Concerns have been raised about delaying the initial exstrophy closure because of late referrals, small templates, or purposeful delay, as practiced at some centers in which the CPRE repair is used to prevent penile ischemia and soft-tissue loss. In a recent large series of 82 patients reported by [Baradaran and colleagues \(2012a\)](#), 33 delayed closures were compared with 59 primary closures in the neonatal period. Longitudinal analysis of bladder capacities demonstrated that compared with neonatal closures, bladder capacities were on average 36 mL smaller in repairs delayed because of small templates and 29 mL smaller in late referrals. However, the rate of bladder growth was the same in all three groups.

Cystoscopy and cystography at yearly intervals are used to evaluate the degree of reflux noted in almost 100% of patients and to provide an estimate of bladder capacity ([Gearhart and Jeffs, 1998](#)). Even in a completely incontinent patient, bladder capacity gradually increases to a point at which the bladder can be distended at cystography to its true capacity. This must be done under anesthesia in young children because the values obtained differ markedly from those obtained when trying to fill the bladder of a crying, squirming infant on an x-ray table ([Gearhart and Jeffs, 1998](#)). If the bladder has not achieved a capacity of at least 30 mL by 1 to 2 years, concern must be voiced to the parents about the overall ability of the bladder to undergo a continence procedure. Currently, the best parameters available to predict overall success are the size of the bladder template at birth and a successful primary closure with absence of infections.

Should bladder outlet resistance be such that urine is retained within the bladder and reflux and ureteral dilation develop with infected urine, it may be necessary to dilate the urethra or to begin intermittent catheterization ([Baker et al, 1999](#)). Sometimes the posterior urethral obstruction can be such that it requires a transurethral incision of the stricture to maintain an adequate posterior urethral outlet. If bladder outlet resistance persists and infections continue, an antireflux procedure may be required as early as 6 months to 1 year after initial closure ([Mathews and Gearhart, 2003](#)). After primary CPRE repair, 50% of patients will require ureteral reimplantation in the first year after closure. Because of this problem, some units are trying ureteral reimplantation at the time of bladder closure, but the numbers of patients treated in this fashion is small ([Braga et al, 2010](#)). If severe upper tract changes occur, surgical revision of the bladder outlet by advancing skin flaps into the orifice or even patching the stricture may be necessary to prevent scarring and further obstruction. As mentioned previously, transurethral incision of the urethral stricture to obtain a balanced outlet should be tried before surgical revision.

Judgment is required to know when to avoid attempts at functional closure and to know when to turn to urinary diversion as a means to preserve renal function. This change of plan is seldom necessary if an adequate outlet has been constructed at the initial closure and if careful attention has been paid to the details of follow-up of the bladder and posterior urethra. An important caveat is that if there are recurrent urinary tract infections (UTIs) and the bladder is distended on ultrasonography, cystoscopy should be performed. The posterior urethra should be carefully examined anteriorly for erosion of the intrapubic stitch, which may be the cause of the recurrent infections ([Baker et al, 1999](#)). If the intrapubic stitch is seen in the posterior urethra, a small suprapubic incision should be made and the stitch should be removed, or, if it can be grasped, it should be removed transurethrally. [Husmann and colleagues \(1990\)](#) have shown very acceptable levels of upper tract function after primary closure as long as prophylactic antibiotics were used after initial closure and elevated urinary residuals were kept below 50 mL. In a recent study by [Schaeffer and colleagues \(2013\)](#), glomerular filtration rate (GFR) was measured before closure and 1

year after bladder neck reconstruction and was found to be no worse or higher than normal values.

Selected Technical Aspects of Other Methods of Closure

Kelly Repair

The multiple-stage Kelly repair begins when the bladder is closed up to the level of the posterior urethra with no attempt to bring the pubic bones into apposition. The second step of the Kelly repair, which differs from other types of repair, is the radical soft-tissue mobilization. This is accomplished by making an incision around the old bladder closure and by making parallel incisions on the urethral plate extending proximally to halfway between the ureteric orifices and the verumontanum. This maneuver helps expose the corpora laterally as they move over toward their insertion onto the pubis. The mucosa lateral to the urethra is excised, as is some of the mucosa of the bladder ([Fig. 139-21A and B](#)). The initial lateral extension of the incision exposes the dorsal nerves of the penis and the attachment of the corpora to the pubis ([Fig. 139-21B](#)). The urethral plate is mobilized from the corporeal bodies and moved to below them to create a penoscrotal hypospadias.

Laterally, the extraperitoneal space behind the rectus is entered and the vas retracted ([Fig. 139-21C](#)). An incision is made in the superior aspect of the pubis downward, creating a “flake” to which medially is attached the corpora of the penis and remnants of the urogenital diaphragm ([Fig. 139-21D](#)). The incision is then taken deeper to the superior aspect of the levator ani. The incision is carried through the levator muscles both deeply and anteriorly to where the levators insert on the back of the pubis. The pudendal vessels and nerves are freed from any attachments. When it appears the entire course has been determined, the flake of the pubis is incised totally and the urethral and bladder neck area and muscles are brought together without tension.

Mitchell Repair

The Mitchell repair, as in all closures, is best performed in the newborn period. The main difference is that the urethra is separated from its attachments to the underlying corporeal bodies and pelvic diaphragm during the first stage of the procedure. Mitchell purports that this allows better posterior positioning of the bladder neck and posterior urethra into the pelvis. This combined bladder closure with penile repair was originally thought to be sufficient for the patient to achieve urinary continence, but this has been found not to be the case in that most of these patients require bladder neck repair ([Gearhart et al, 2005](#); [Shoukry et al, 2009](#); [Gargollo et al, 2011](#)).

The closure is begun in the standard fashion, but the incision is carried out onto the urethral plate, taking care to preserve its blood supply and avoiding corporeal injury. The penis is then disassembled into three components—the right corpus, left corpus, and urethral wedge ([Fig. 139-22A](#))—because it is believed that each corpora has its own blood supply. However, the urethral plate draws blood from spongiosa so there can be ischemia. The dissection moves cranially and the intersymphysal band is incised. This is also accomplished as in the MSRE procedure by going medial to the inferior aspect of the pubis and cutting these fibers from their posterior urethral attachment all the way down to the levator hiatus ([Gearhart et al, 2007](#)). During standard closure of the bladder, the bladder neck is tailored and the urethra is closed in an attempt to move the urethra to the tip of the penis ([Fig. 139-22B](#)). If it does not reach the tip of the penis, the urethra is taken to the base of the penis in a hypospadiac position in a majority (70%) of patients ([Fig. 139-22D](#)).

The repair is very similar in the female patient, with care taken to mobilize the bladder neck, urethra, and vagina as a single unit. Unlike the Kelly repair but similar to MSRE, an osteotomy is used in both sexes if the child is older than 3 years or the diastasis is judged to be excessive.

Figure 139-21. Kelly repair. A, The penis has been degloved and pulled down over the scrotum. The corpora are exposed with their attachments to the pubis. The dorsal nerves of the penis are identified emerging from the pelvis superior to the attachment of the corpus to the pubis. B, The extraperitoneal plane behind the left rectus muscle has been opened. The vas is identified and retracted with peritoneum. The external iliac vessels and obturator vessels and nerves are identified. The initial incision is made into the pubis to create a flake of bone, taking care to go down only to the level of the emergence of the dorsal nerve of the penis. C, The pelvic floor is opened, and the bladder and rectum retracted medially. An incision is made through the levator medial to the white line. This incision is taken out to the wall of the pelvis so the attachment of the levator to the back of the pubis will be moved with the bone flake. D, Deeper, the ischiorectal fossa is encountered where the pudendal vessels are identified and freed up. Once the vessels and bone flake are totally free, the tissues of the penis, bladder neck, and urethra are reconstructed. (A and B, Redrawn from Kelly with permission.)

Penile and Urethral Closure in Exstrophy

Epispadias Repair

Historically, bladder neck reconstruction was performed before penile and urethral reconstruction. An increase in bladder capacity in patients with extremely small bladder capacities after epispadias repair prompted a change in the management program (Gearhart and Jeffs, 1989a) (see Fig. 139-19). In a group of patients with a small bladder capacity after initial closure, there was a mean increase of 55 mL in males only 22 months after epispadias repair. However, with MSRE, the epispadias repair is now performed at about 6 to 10 months of age in all patients. Recent data by Kufner and colleagues (2010) clearly demonstrated better eventual overall bladder capacity in patients in whom the epispadias repair was completed before 12 months of life. With this modification, possibly all patients can achieve an appropriate capacity by the time they are physically and mentally ready to undergo bladder neck reconstruction. Because most boys with exstrophy have a somewhat small penis and a shortage of available penile skin, all patients undergo testosterone stimulation before urethroplasty and penile reconstruction (Gearhart and Jeffs, 1987).

Many techniques have been described for reconstruction of the penis and urethra in patients with CBE. Current methods of epispadias repair in bladder exstrophy are the Cantwell-Ransley repair (1989), the modified Cantwell-Ransley repair (1995), and the penile disassembly technique described by Mitchell and Bāgli (1996).

Regardless of the surgical technique chosen for reconstruction of the penis in bladder exstrophy, four key concerns must be addressed to ensure a functional and cosmetically pleasing penis. These concerns are (1) correction of dorsal chordee, (2) urethral reconstruction, (3) glanular reconstruction, and (4) penile skin closure.

Although it is possible to achieve some penile lengthening and release of chordee at the time of initial closure, it is always necessary

to perform formal penile elongation with release of chordee at the time of urethroplasty in exstrophy patients. Data of Silver and associates (1997b) clearly showed that this is more of an apparent lengthening of the penis than a true lengthening because the anterior corporeal bodies in exstrophy patients have 50% less length than age-matched controls. All remnants of the suspensory ligaments and old scar tissue from the initial bladder closure must be excised. Further dissection of the corpora cavernosa from the inferior pubic ramus can be achieved. It is often surprising how little is accomplished in freeing the corporeal bodies from the pubis at the time of initial exstrophy closure (Gearhart, 1991).

Lengthening of the urethral groove is also essential. In the penile disassembly technique described by Mitchell and Bāgli (1996), the urethral plate is dissected completely from the glans; in over 70% of patients it is not long enough to reach the tip of the penis, and as a result hypospadias is present, with further reconstruction needed at another time (Hafez and el-Sherbiny, 2005).

Chordee

Besides lengthening of the urethral groove, dorsal chordee must be addressed. To release dorsal chordee, one may lengthen the dorso-medial aspect of the corpora by incision and anastomosis of the corpora themselves (Gearhart et al, 1992). Also, length can be gained by placement of a dermal graft to allow lengthening of the dorsal aspect of the corpora (Woodhouse, 1986). However, most of these techniques, especially grafting, are reserved for patients who are seen in adolescent and adult years for epispadias surgery with the need for some increased penile length and correction of residual chordee.

Urethral Reconstruction

Urethral reconstruction is an important aspect of external genital reconstruction in exstrophy. This can be accomplished by many

Figure 139-22. Mitchell repair. A, Corporeal separation with dissection of urethral plate to complete penile disassembly. B, Tailoring of bladder neck in complete primary repair of exstrophy procedure. C, Urethral plate tubularization done with interrupted sutures in an attempt to lengthen it. D, Reapproximation of pubic symphysis with medial rotation of the corpora and placement of tubularized urethra underneath corpora either on or below glans in a hypospadiac position. (A, C, and D, Redrawn from Grady with permission.)

previously reported methods, most of which have been abandoned: (1) tubularization of dorsal urethral groove; (2) free grafts of genital and extragenital skin; (3) ventral transverse island flaps; and (4) double-faced ventral island flaps. Most modern techniques of epispadias repair associated with bladder exstrophy use tubularization of the urethral plate, moving the urethral plate under the corporeal bodies after closure to lessen the incidence of urethrocutaneous fistula, to give the penis a more downward deflection, and to make a more easily catheterizable urethral channel (Surer et al, 2000). With the penile disassembly technique, interrupted sutures are often used to try and get the urethra to the tip of the penis again after it is completely detached, with resultant hypospadias in many. Although some authors have described the ease and success of hypospadias repair after penile disassembly (Shnorhavorian et al, 2008), a good-sized European study (Berrettini et al, 2011) found quite the opposite with a 50% complication rate. Patients who did well underwent a two-stage repair and placement of a graft before urethroplasty.

Our preference for urethroplasty and penile reconstruction, if the urethral groove has adequate length, is the modified Cantwell-Ransley repair (Gearhart et al, 1992, 1995c, 2005) (Fig. 139-23).

Currently, in the modern applications of the staged reconstruction of bladder exstrophy, epispadias repair is performed when the child is 6 to 10 months of age. At the time of primary closure the urethra is closed well up on the penile shaft.

The modified Cantwell-Ransley procedure is begun by placing a transverse stitch through the glans as a traction stitch. Incisions are made over two parallel lines marked previously on the dorsum of the penis that outline an 18-mm-wide strip of urethral mucosa, extending from the prostatic urethral meatus to the tip of the penis (Fig. 139-24A). For this procedure, a deep vertical incision is made in the urethral plate distally. The incision is then closed with 6-0 polyglycolic sutures in a transverse fashion (Fig. 139-24B to D). This procedure flattens the distal urethral plate and advances the urethra to the tip of the phallus so that it will be in excellent glanular position when the glanular wings are closed over the reconstructed urethra. Glanular mucosal areas of the dorsal glans are excised adjacent to the urethral strip, and thick glanular flaps are constructed bilaterally (Fig. 139-24F). Lateral skin flaps are mobilized and undermined. A Z incision of the suprapubic area permits wide exposure and division of the suspensory ligaments and old scar tissue from initial exstrophy closure (Fig. 139-24F).

Ventral penile skin is taken down to the level of the scrotum (Fig. 139-24E). Care is taken to preserve the mesentery to the urethral plate, which arises proximally and extends upward between the corporeal blood supply to the urethral plate. Dissection of the corpora is begun ventrally with dissection on the surface of Buck fascia covering the corporeal bodies. The plane is followed closely until one exits on the dorsum of the penis between the corpus spongiosum and the corporeal body, first on one side and then on the other (Fig. 139-24F and G). Vessel loops are placed around the corporeal bodies, and the dissection is extended proximally on the corpora to dissect the urethral plate free from the corporeal bodies up to the level of the prostate. Although one might expect difficulties when dissecting proximally where the paraexstrophy skin flaps had been sutured to the urethral plate, this has not been encountered

in our experience, and dissection is kept just on the corporeal bodies while proceeding proximally. The urethral plate is also dissected distally past the level of the junction of the glans with the corporeal bodies. In this manner, adequate mobilization is obtained, and it is not difficult to bring the corporeal bodies over the urethra at the level of the corona. This separates the penis into three components: the two corpora and the urethral plate (Fig. 139-24F). Complete penile disassembly is not undertaken, because the most distal 1-cm attachment of the mucosa plate to the glans is left intact (Surer et al, 2000).

The neurovascular bundles, situated between Buck fascia and the corporeal wall, are typically left intact in young patients if rotation of the corporeal bodies over the urethra effectively straightens the penis. If not, the neurovascular bundles are dissected free from the

Figure 139-24, cont'd G, Posterior urethra and bladder neck are reconstructed. H and I, Bladder muscle is brought together in a double-breasted fashion over the neourethra. J, Bladder closure is completed and the distal suspensory sutures are tied over the abdominal wall (see inset). Suprapubic tube and stents are left in place; however, the urethra is left unstented. (© Brady Urological Institute.)

corporeal bodies, with vessel loops being placed around these structures so that the neurovascular bundles will not be compromised when incisions are made in the corpora and the corpora are rotated medially over the neourethra (Fig. 139-24H). After the corporeal bodies are incised or rotated over the urethra, the urethral strip is closed in a linear manner from the prostatic opening to the glans over an 8-Fr silicone stent with 6-0 polyglycolic acid sutures. After this is accomplished, incisions are made in the corporeal bodies at the point of maximum curvature, opening a diamond-shaped defect in the erectile tissue (Fig. 139-24H). The corpora are then closed over the neourethra with two running sutures of 5-0 PDS, and the diamond-shaped defects in the adjacent area of the corpora are sutured to each other. This procedure effectively displaces the urethra ventrally in a normal position. This not only causes the downward deflection of the penis but also allows some additional length by dorsal rotation and approximation of the corporeal bodies over the neourethra. After the urethra has been transferred to the ventrum, further sutures of 4-0 polyglycolic acid are placed between the corporeal bodies to bury the urethra further, especially at the level of the junction of the glans and the corporeal bodies at the corona (Fig. 139-24I).

The glans wings are then closed over the glanular urethra using subcuticular sutures of 5-0 polyglycolic acid, and the glans epithelium is closed with 6-0 polyglycolic acid sutures (Fig. 139-24I). The ventral skin is then brought up and sutured to the ventral edge of the corona, and the flaps are fashioned to provide adequate

coverage and lengthening of the dorsum of the penis. The skin is reapproximated with interrupted 5-0 or 6-0 polyglycolic acid sutures (Fig. 139-24K to M). A Z-plasty at the base of the penis is closed with interrupted 5-0 or 6-0 polyglycolic acid sutures. A silicone stent is left indwelling in the neourethra to provide drainage for 10 to 12 days (see Fig. 139-24).

Penile Skin Closure

If skin closure continues to be a problem in genital reconstruction owing to the paucity of skin associated with this condition, a Z-plasty incision and closure at the base of the penis prevents skin contraction and upward tethering of the penis. The ventral foreskin can be split in the midline and brought to the dorsum as lateral preputial flaps for coverage of the penile shaft. If the flaps are a bit asymmetrical, a staggered dorsal suture line results, with less upward tethering. Alternatively, a buttonhole can be created in the ventral foreskin and simply transposed to the dorsum for additional penile skin coverage. All patients in our series are given testosterone enanthate 2 mg/kg intramuscularly 5 weeks and 2 weeks before repair.

Postoperative Problems

Postoperative pain and bladder spasms after extensive external genital reconstructive surgery require a combined effort of the

pediatric anesthesia pain service and the surgical service. Controlling bladder spasms is paramount because they are associated with urinary extravasation and fistula formation. All of our patients have a caudal epidural catheter placed at the time of surgery, and oxybutynin is started immediately after surgery to decrease the incidence of bladder spasms and enhance the patient's comfort. At the time of discharge, the plastic dressing on the penis is left intact and the child is discharged with narcotics, antispasmodics, and appropriate broad-spectrum antibiotic coverage.

Female Exstrophy

The principles of repair of female and male exstrophy are similar. However, in the female patient we recommend the following: (1) radical dissection of the bladder and urethra from surrounding structures while connection to the vagina is maintained; (2) dissection of the lateral aspects of the posterior vesicourethral and vaginal unit from their attachments to the pelvic floor; (3) tension-free closure of the abdomen, bladder-urethra, and external genitalia; and (4) judicious use of osteotomy and proper immobilization of the pelvis and extremities.

As in the male patient, if the pelvic bones are separated over 4 cm or are not malleable under anesthesia, an osteotomy is then performed. The transverse innominate osteotomy along with vertical iliac osteotomy is commonly used in our practice. Interfragmentary pins are placed and the fixator is applied after the soft-tissue surgery has been completed. An interesting finding in over 1287 exstrophies in our institutional-approved database is that even with a large bladder template the diastasis tends to be narrower in female than in male patients. Thus, closure in female exstrophy patients is easier to perform, and female patients do not require an osteotomy as commonly as male patients.

The vagina is prepared with an iodine preparation so that if it is violated during the dissection it can simply be closed. In the closure, we start our dissection along the medial aspect of the clitoral or corporeal halves and move deeply into the pelvis. Pinpoint electrocautery at a low setting is used to limit both bleeding and tissue injury. The dissection of the vagina proceeds laterally and posteriorly. The urethrovaginal septum is left intact to preserve its blood supply. As in the male patient, the dissection proceeds posterior and downward until the levator hiatus is reached, with the urogenital diaphragm fibers lateral and posterior to the vesicourethral plate and vaginal incision. This maneuver allows placement of the unit deeply into the pelvis and, more important, keeps it from being displaced anteriorly when the pelvic bones are brought together.

The bladder is closed with a single figure-of-eight layer of 3-0 polyglactin suture to maximize postclosure bladder volume. The urethra is closed with a single layer of 4-0 to 5-0 polyglactin depending on the thickness of the tissue. An indwelling suprapubic tube is brought out through the dome of the bladder along with two small feeding tubes that act as stents and are left in place for 4 full weeks. These exit the neoumbilicus as described by Hanna (1986). No tubes are brought out through the neourethra because this can be associated with wound infection and prolapse or dehiscence. A No. 2 nylon suture in a horizontal mattress fashion is used to bring the pubic bones into apposition. Once the pubic bones are brought together, a routine subcutaneous and skin closure are performed. A mons plasty is then performed, and the subcutaneous tissue of the clitorides are brought together with 5-0 polyglactin and the epithelium with 6-0 polyglactin sutures. If needed a Y-V labioplasty is performed for better exteriorization of the vaginal introitus.

If an osteotomy has been performed, the external fixator is then placed and a pelvic x-ray study obtained. If pin and fixator placement are optimal, then the infant is placed in modified Buck traction for 4 weeks. If an osteotomy was not performed, the infant is placed in Bryant traction for 4 weeks. Postoperative care is the same as in the male patient, with an indwelling epidural catheter and bladder spasms controlled by both the epidural and oral oxybutynin.

Continence and Antireflux Procedure

Although some modern exstrophy repair methods are claimed to establish suitable continence without formal bladder neck repair, many patients are referred to our unit still incontinent after only prior newborn repair or after newborn repair and multiple injections of various substances into the bladder neck area. Likewise, other groups have reported their outcomes with newborn repair, and most have recommended some sort of outlet procedure. In our unit each child has a cystoscopy and gravity cystogram under anesthesia yearly after newborn closure to assess bladder growth. Prior data by Gearhart and Jeffs has shown that after newborn exstrophy closure there should be an average increase in bladder capacity of 54 mL in 24 months (Gearhart and Jeffs, 1989b). Chan and colleagues (2001) found that in selected exstrophy patients who underwent closure, epispadias repair, and bladder neck reconstruction at our institution, a median bladder capacity of 100 mL was more common in the group of patients who were completely dry after bladder neck reconstruction. Most of these children were 5 to 7 years of age and were ready emotionally, maturationally, and intellectually to participate in a postoperative voiding program. An intense pre-bladder neck repair program is conducted by a senior urology nurse practitioner, senior clinical nurses, and a child psychologist well versed in voiding issues. These sessions are begun for both child and parents at least 6 months before an outlet procedure. Successful completion of the program is required before surgery is scheduled.

Continence and antireflux procedures performed at our institution are illustrated in Figure 139-23. The bladder is opened through a transverse incision at the bladder neck with a vertical extension. The later midline closure of this incision is the width of the bladder neck and enlarges the vertical dimension of the bladder, which in exstrophy is often short (see Fig. 139-23A). A Cohen transtrigonal ureteral reimplantation or a cephalotrigonal reimplantation is performed to move the ureter across the bladder, above the trigone, or to direct the ureter cephalad up onto the edge of the trigone (see Fig. 139-23B and C) (Canning et al, 1992). If the ureters are low on the trigone and there is a need to move the ureteral hiatus higher, the hiatus is simply cut in a cephalad direction, and cross-trigonal reimplants are performed at the upper aspect of the trigone (see Fig. 139-23C).

The continence procedure is begun by selecting a posterior strip of mucosa 15 mm wide and 30 mm long that extends distally from the mid-trigone to the prostate or posterior urethra (see Fig. 139-23D). Bladder muscle lateral to the mucosal strip is denuded from the mucosa. It is often helpful at this juncture to use one or two epinephrine-soaked sponges to aid in the control of bleeding and the visualization of the denuded area. Tailoring of the denuded lateral muscle triangles is aided by multiple small incisions on the free edge bilaterally that allow the area of the reconstruction to assume a more cephalad position (see Fig. 139-23E). These muscle flaps not only are smaller but also are not incised transversely at their cephalad extent as described in the original Young-Dees procedure to prevent denervation and ischemia. The basic premise is to create a mucosa-lined tube inside a muscular funnel that narrows from its junction with the floor of the bladder that extends caudally. The edges of the mucosa and underlying muscle are closed with interrupted sutures of 4-0 polyglycolic acid (see Fig. 139-23F). The adjacent denuded muscle flaps are overlapped and sutured firmly in place with a 3-0 PDS to provide reinforcement of the bladder neck and urethral reconstruction (see Fig. 139-23G to I). An 8-Fr urethral stent may be used as a guide during posterior urethral and bladder neck reconstruction but is removed after the repair is completed. After the bladder neck repair is completed, the repair is suspended to the rectus fascia (see Fig. 139-23J, inset).

Very radical dissection of the bladder, bladder neck, and posterior urethra is required, not only within the pelvis but also from the posterior aspect of the pubic bar to provide enough mobility for the bladder neck reconstruction. This maneuver allows adequate bladder neck narrowing and tightening of the bladder neck repair and subsequent anterior suspension of the newly created posterior urethra and bladder neck. In patients who are presented after CPRE repair in the newborn period and who had

a vesicocutaneous fistula after closure, great care must be taken anteriorly during mobilization of the bladder neck because the tissues are more adherent to the back of the intrasymphyseal bar. If visualization of the posterior urethra is problematic, the intrasymphyseal bar can be cut, thus providing a widened field of exposure. The intrasymphyseal bar is approximated with 2-0 sutures of PDS. If the intrasymphyseal bar is cut, abduction of the lower extremities should be restricted in the postoperative period to allow proper healing of the intrasymphyseal bar.

Postoperative Care

Ureteral stents are placed in the reimplanted ureters and brought out through the wall of the bladder, and the bladder is drained by suprapubic tube, which is left indwelling for a 3-week period. At the end of 3 weeks the suprapubic tube is clamped and the patient is allowed to attempt to void. Initially, the tube should not be clamped for more than 1 hour. If voiding does not occur, the child is given an anesthetic and an 8-Fr Foley catheter is placed. This is left in place for 5 days, then removed, and another voiding trial is begun. This part of the postoperative period is most demanding on the patient and family. Some children require several catheter placements before voiding is initiated. If the child can empty the bladder satisfactorily, the suprapubic tube is removed. Frequent bladder and renal ultrasound examinations are required in the first few months after bladder neck repair.

MODERN INITIAL REPAIR OF BLADDER EXSTROPHY: OUTCOMES AND RESULTS

The use of functional reconstruction in bladder exstrophy has resulted in dramatic improvement in the success of reconstruction. Several series (Purves et al, 2008; Shnorhavorian et al, 2008) have demonstrated the success and applicability of early newborn closure with or without pelvic osteotomy. Important older series have shown acceptable continence rates with preservation of renal function in a majority of patients treated in early life.

Two of the most reliable predictors of eventual urinary continence are the size of the bladder template at birth and a successful primary closure. Regardless of the technique used, a complication-free newborn closure of the abdomen, pelvis, bladder, and proximal or complete urethra paves the way for an optimal long-term result. A very large series by Surer and colleagues (2001) demonstrated in a large group of exstrophy patients who underwent early closure the importance of a successful primary closure. Sixty-eight patients (57 male and 11 female patients) were referred for bladder neck reconstruction after primary closure at other centers. Twenty percent had concomitant pelvic osteotomy at the time of closure. The majority of patients underwent closure within the first 72 hours of life. Mean capacity at the time of bladder neck repair was 121 mL. Eighty-three percent are continent and voiding per urethra. This application of early successful closure and follow-up reconstruction by a second surgeon shows convincingly that a successful primary closure is one of the most important determinants of eventual bladder capacity and continence regardless of who originally performed the repair.

Initial Closure

Long-term data on all modern types of exstrophy repair can be difficult to obtain. Nonetheless, this section will deal with what has been gleaned from the recent literature. Most data come from the MSRE and CPRE groups. In a large series reported by Hernandez and colleagues (2008), clinical information from 189 patients who had undergone primary closure between 1988 and 2004 was extracted from our exstrophy database. The records of 131 patients (95 males) who underwent MSRE with a modified Cantwell-Ransley repair by a single surgeon in 1988 to 2004 were reviewed with a minimum 5-year follow-up. The importance of a successful initial closure is emphasized by Oesterling and Jeffs (1987) and Husmann

and colleagues (1989a), who found that the onset of continence was quicker and the continence rate higher in those who underwent a successful primary closure with or without osteotomy. In addition, Novak and colleagues (2010) reported on patients with bladder exstrophy who underwent more than one attempt at primary closure. If a patient underwent two closures, the chance of having an adequate bladder capacity for bladder neck repair was 60% and the chance of voided continence was 17% overall. Patients who underwent three closures had only a 50% chance of an adequate capacity and less than a 16% chance of voided continence. In an evaluation of this select group, it was found that at the time of primary closure, 80% of patients had no form of pelvic osteotomy. Thus, the chance of achieving an adequate bladder capacity and eventual continence after more than one exstrophy closure is markedly diminished. These very poor results underline the paramount importance of a secure abdominal, bony pelvis and posterior vesicourethral unit in the newborn with exstrophy.

Also, compared with many of the other repairs, data are available from several units on their results with the CPRE repair. In a series by Shnorhavorian and colleagues (2008), 2 of 39 patients had dehiscence of the fascia and 9 of 39 developed a vesicocutaneous fistula. Complications seen in the CPRE repair are as much as those seen in MSRE. However, some are particular to this repair. A large series of vesicocutaneous fistulae was reported from a single institutional study; some patients had an osteotomy, and others did not (Shoukry et al, 2009). In addition, several series have reported the need for early ureteral reimplantation after closure and the occurrence of significant upper tract changes in many patients (Grady and Mitchell, 1999). This has prompted the call for ureteral reimplantation at the time of exstrophy closure by one group (Braga et al, 2008).

Although many earlier published series were small, the incidence of bladder prolapse and dehiscence is reported to be low. However, in a recent large series of primary CPRE repairs by Shoukry and colleagues (2009), the incidence of major prolapse and dehiscence was 15.8% even with the use of osteotomy. In this author's series we have seen a number of referred patients with complete dehiscence and major bladder prolapse after newborn CPRE repair. However, the other complicating factors we have seen, in addition to the aforementioned, have been significant losses of soft tissue including partial or complete loss of the penile glans in 9 patients and the loss of the urethrovaginal septum in 2. In a series by Hamouda (2003), 5 of 42 patients had ischemic loss of glans tissue after CPRE repair. Thus, the complications of closure between CPRE and MSRE are similar, but much more serious if soft-tissue loss occurs.

Baka-Ostrowska and colleagues from Warsaw (2013) reported on 100 primary closures. Complete dehiscence occurred in 31 patients, of whom 24 had no osteotomy and 7 a posterior iliac osteotomy only. Of those who were newborns and underwent closure at less than 72 hours ($n = 47$) and in whom no osteotomy was performed, dehiscence occurred in 13 patients. All were immobilized with a modified spica "chair" cast for 3 weeks and then an elastic bandage for 3 weeks. These authors now recommend osteotomy for all newborns with a diastasis greater than 5 cm and in those undergoing closure after 72 hours.

In a recent publication of the Erlangen repair by Rosch and colleagues of 100 closures, the complications in general were mild, with urethrocutaneous fistulae in 2%, minimal hydronephrosis in 20%, and severe hydronephrosis requiring further surgery in 3% (Rosch et al, 2001). There were no incidents of bladder prolapse or dehiscence. Osteotomy was not used in any patient, but a very sophisticated coaptation technique involving the obturator foramen was used in all patients.

In a report by Kelly and colleagues (2008) of 26 patients undergoing Kelly repair, there was a reported incidence of bladder prolapse requiring treatment in 25%. Soft-tissue loss of glanular tissue was noted in 2 of 26 patients.

Interest in the outcomes of exstrophy closure has expanded to interest in the economic outcomes of the treatment of this major birth defect and who should be doing these types of operations

in the newborn. In a paper by [Nelson and colleagues \(2005\)](#), high-volume hospitals (those closing more than five exstrophies per year) had lower overall costs per patient than low-volume hospitals (fewer than five exstrophies per year). In addition, [Nelson and colleagues \(2008\)](#) found that a successful newborn closure had overall markedly lower inflation-adjusted hospital charges than reclosures owing to shorter operating times and shorter length of stay.

A corollary to these papers was one from [Meldrum and colleagues \(2005\)](#), who found that when exstrophy closures failed and the exstrophy had to be reclosed, the success rates and ultimate continence were better in patients of fellowship-trained pediatric urologists than those of other surgeons (general urologists, non-fellowship-trained pediatric urologists, and general pediatric surgeons).

In the evaluation of this group of selected exstrophy patients, it was found that at the time of initial closure, 19 of 23 patients had no osteotomy. Six of the patients had obtained bladder capacity suitable for bladder neck reconstruction; three were dry, and three were incontinent. Bladder size was inadequate in 9 patients who had been monitored for bladder growth. The chance of achieving an adequate bladder capacity and eventual continence after more than one closure attempt is markedly diminished. Lastly, the importance of early initial closure was emphasized by [Husmann and colleagues \(1989a\)](#), who showed that only 10% of the patients who undergo bladder closure before 1 year of age but 40% of those who undergo the procedure at a later age require eventual augmentation.

Epispadias Repair

Although urinary incontinence remains the most significant problem for patients with CBE and epispadias, anxiety about inadequate and unattractive genitalia still poses the greatest concern to male patients. We began using the modified Cantwell-Ransley repair in patients with classic exstrophy or epispadias in 1988 and have reported our early experience ([Gearhart et al, 1992, 1995c](#)).

Since 1988, the modified Cantwell-Ransley repair has been performed for 129 male patients with either CBE (97 patients) or epispadias (32 patients) ([Baird et al, 2005b](#)). At the time of surgery, the patients' ages ranged from 1 to 18 years with an average age of 19 months. Of the 97 patients with bladder exstrophy, 31 had a short urethral groove requiring paraexstrophy skin flaps for penile lengthening at the time of initial bladder exstrophy closure. Of the 32 epispadiac patients, 26 had penopubic and 6 had penile epispadias at presentation.

This technique was used for primary urethroplasty in 106 patients with bladder exstrophy and 32 with epispadias. The modified Cantwell-Ransley repair was used as a secondary procedure after failed urethroplasty in 15 patients with exstrophy and 8 with epispadias and was combined with reclosure of bladder exstrophy in 18 patients. Early epispadias repair was performed when the patients were 6 months to 1 year of age. However, because of concerns about getting the urethra deeper under the corpora at the glanular level, beginning in 1994 we further modified the Cantwell-Ransley repair by detaching the mucosal plate from the corona except for the distal 0.5 to 1 cm of the plate inside the glans.

One hundred twenty patients had a horizontal or downward-angled penis while standing. The incidence of urethrocuteaneous fistula in the immediate postoperative period was 16%, and at 3 months it was 12%. Nine patients developed a urethral stricture of the proximal anastomotic site, and 12 had minor skin separation of the dorsal skin closure. Cystoscopy with catheterization in 120 patients revealed an easily negotiable channel in all. Eight patients required further penile straightening surgery. Fifteen patients older than 16 years had engaged in satisfactory intercourse, and all reported orgasms and ejaculation with a straight penis on erection. One patient reported that his penis was shorter after surgery.

Modern penile reconstructive techniques should create a straight and functional penis with a glanular meatus, an easily catheterizable neourethral channel (if needed), and an acceptable cosmetic appearance. Many adolescents considered their odd-appearing

genitalia with a short, widened penis upwardly deviated to be a greater psychosocial problem than incontinence, and therefore every effort should be made to restore the penis to a normal condition. In 1989, Ransley and associates introduced a concept to release dorsal chordee by incision and anastomosis of the dorso-medial aspect of the corpora over the urethra and urethral meatotomy at the distal end of the glans, to move the meatus to a more normal position and secure good direction of the urinary stream (reverse MAGPI [meatal advancement and glansplasty incision]) ([Ransley et al, 1989](#)). Ransley's group has reported its long-term experience with 95 patients in whom the modified Cantwell-Ransley repair was used: fistula occurred in only 4% of patients, and a urethral stricture in only 5% ([Kajbafzadeh et al, 1995](#)).

Dissection of the urethral strip to inside the glans penis provides a ventral position of the urethra and the glans and submerges the urethra well below the corpora at the glans level. This approximation of raw surface of glanular tissues dorsally over the urethra is clearly why the incidence of fistula in the area of the corona is very rare compared with the Young repair. Fistulae in our patients usually appear at the base of the penis, where the urethra comes up proximally between the corporeal bodies. In modern exstrophy reconstructive techniques, most surgeons try to preserve the urethral plate at the time of exstrophy closure. Because the use of paraexstrophy skin flaps has been noted to be associated with the development of strictures, the use of these flaps is limited to selected patients in whom penile lengthening cannot be achieved with standard techniques.

Papers from several institutions have reported their results with the Mitchell-Bagli penile disassembly technique. Complications are very similar to those of other methods of epispadias repair (i.e., fistula and urethral stricture) ([Zaontz et al, 1998](#); [Kibar et al, 2009a](#)). Although not a complication, a high percentage are made hypospadiac as the completely dissected urethral plate fails to reach the tip of the glans. The rate of being made hypospadiac has been reported as 38% to 83%. ([Mitchell and Bagli, 1996](#); [El-Sherbiny and Hafez, 2005](#)).

As mentioned in the prior section on exstrophy closure, ischemic loss of the glans, urethral plate, and corpora have been reported by [Hammouda \(2003\)](#) and [Husmann and Gearhart \(2004\)](#) after penile disassembly. [Cervellione and colleagues \(2010\)](#) have reported the largest series of penile ischemic injury in the exstrophy-epispadias spectrum. Most occurred at the time of exstrophy closure, and 19 of 24 did not have a pelvic osteotomy. The suggested explanation by the authors was compression of the pudendal vessels owing to tension after pelvic apposition and/or direct injury to the pudendal vessels. Stopping the closure and doing an immediate osteotomy while the vessels had time to regain flow was the recommended course of action.

Repair of the hypospadias in these patients has been reported by the Seattle group as not difficult or associated with major complications. However, data from [Hafez and El-Sherbiny \(2005\)](#) and [Gearhart and Baird \(2005\)](#) shows that difficulties can be associated with these repairs. In an attempt to deal with the issues and prevent them, [El-Sherbiny and Hafez \(2005\)](#) and [Perovic and colleagues \(1999\)](#) have modified the Mitchell repair to resemble the modified Cantwell-Ransley repair ([Gearhart and Baird, 2005](#)) by keeping the urethral plate attached to the distal glans to obviate the need for making the child hypospadiac at the time of isolated epispadias repair or when associated with CPRE.

In our opinion, none of the current epispadias repairs offers any significant gain in penile length by removal of the entire urethral plate from the glans or even the use of a free graft. Data reported by [Silver and colleagues \(1997b\)](#) clearly showed that although anterior corporeal length is significantly less in patients with exstrophy, posterior corporeal length is normal. These findings suggest that penile lengthening procedures at the time of epispadias repair improve apparent penile length and straighten the penis but do not transfer additional tissue (i.e., length) to the corporeal bodies. We have observed that the modified Cantwell-Ransley repair effectively corrects corporeal chordee and adds some penile length, and it can be hoped that dorsal penile curvature,

§Patients reported that they were dry for more than 3 hours during the daytime.

often seen at puberty, will be lessened. In our significant experience with adolescent exstrophy males with significant dorsal chordee, we agree with [Perovic and colleagues \(1999\)](#) that movement of the neurovascular bundles along with incision and grafting of the resultant defect gives better results long term than incision and corpora cavernostomy. Typically in our experience, incision and rotation are used only for older patients with marked chordee. In the patients in whom corporeal rotation is used without corporeal incision and anastomosis, the neurovascular bundle is left intact and not dissected from its bed. Although review of findings reveals that almost all penises are straight or deflected downward, many of these patients are still young children. The long-term assessment of penile and urethral reconstruction in exstrophy patients by the modified Cantwell-Ransley repair has shown that in patients with bladder exstrophy and epispadias there is some increase in penile length, and a relatively straight penis with an adequate urethral caliber, which is adequate to void and ejaculate through, can be achieved with minimal morbidity. Long-term reports with the penile disassembly technique have also demonstrated a reasonably straight penis ([Grady, 2003](#)).

Bladder Neck Repair

Bladder neck reconstruction results in the exstrophy population have been reported by several groups. Some extensive experiences have come from the European groups in Lyon and Paris. [Mouriquand and associates \(2003\)](#) reported on 80 children with bladder exstrophy and 25 with incontinent epispadias. Follow-up ranged from 1 to 11 years. Forty-five percent of the group with exstrophy and 52% of those with epispadias had a dry interval longer than 3 hours. Although the continence rate was low, many of the exstrophy patients did not undergo closure until 6 to 12 months of age. Many underwent epispadias repair after bladder neck reconstruction, a factor known to influence both eventual capacity and continence. [Lottmann and colleagues \(1998\)](#) presented a long-term follow-up study of Cendron's exstrophy patients who underwent complete reconstruction. With the Young-Dees repair, [Lottman and coworkers \(1998\)](#) were able to achieve urinary continence in 71% of male patients and 53% of female patients. Overall continence was 65% with a mean follow-up of 12 years after bladder neck repair. Series from North America using mainly the classic Young-Dees-Leadbetter repair reported continence rates ranging from 60% to 82% ([Husmann et al, 1989a; Mergurian et al, 1991; Perlmutter et al, 1991; Franco et al, 1994; McMahon et al, 1996; Chan et al, 2001; Cole et al, 2003](#)) (Table 139-1). The most important long-term factor gleaned from a review of all these series is the fact that bladder capacity at the time of bladder neck reconstruction is the most important determinant of eventual success.

Records of 95 patients who underwent all stages of MSRE by a single surgeon at our institution between 1988 and 2004 were reviewed by [Baird and colleagues \(2007\)](#). Sixty-seven patients with bladder neck reconstruction and minimum 5-year follow-up were available for analysis. The current voiding status of each patient was obtained from parental or patient interview or direct observation by the nursing and physician staff. The patients were categorized as spontaneous voiding not on intermittent catheterization and were

TABLE 139-2 Urinary Continence after 67 Initial Bladder Neck Reconstructions

RESULT	AVERAGE DRY INTERVAL	NO. OF PATIENTS	% OF PATIENTS
Continent	3 Hours	47	70%
Social continence (dry daytime, occasional wet nights)	3 Hours	7	10%
Wet	<3 Hours	13	19%

assigned a status of (1) completely dry—day and night; (2) socially continent—dry at least 3 hours during the day with occasional wet nights; or (3) wet—dry for less than 3 hours during the day and wet at night (Table 139-2).

Of the 67 male patients who underwent bladder neck repair, the mean age for primary closure was 4 months (range 6 hours to 4 months). The mean age at bladder neck repair was 4.8 years (range 40 to 60 months), and these patients had a mean bladder capacity before repair of 98 mL (range 75 to 185 mL). Of the 67 patients, 47 (70%) are continent and voiding urethrally without the need for augmentation or intermittent catheterization. Seven patients (10%) had social continence with occasional wet nights. The renal units of all patients who underwent bladder neck repair were evaluated by intravenous pyelography or ultrasound postoperatively on multiple occasions to assess preservation of renal function after the outlet procedure. One patient had reflux and hydronephrosis after the outlet procedure and bilateral reimplantation and developed left pyelonephritis with resultant mild scarring. Dimercaptosuccinic acid (DMSA) scanning revealed nearly normal bilateral function. Conservative follow-up revealed resolution of the reflux with time. One patient developed ureteral obstruction and required reoperative reimplantation. Prolonged outlet obstruction required cystoscopy and placement of an 8-Fr catheter in 19 patients, and prolonged suprapubic drainage was required in 13 patients. Thirteen (19%) failed bladder neck repair completely; 6 have undergone continent diversion, and 7 await further surgery. The mean time to daytime continence was 14 months (range 4 to 23 months), and the mean time to nighttime dryness was 23 months (range 11 to 34 months). No correlation was found between age at bladder neck reconstruction and age at achievement of continence.

The findings in this series were that continence was more likely in patients who underwent primary exstrophy closure before 72 hours of age or after 72 hours of age with an osteotomy. These results coincide with those of [Husmann and colleagues \(1989a\)](#), who found that patients who underwent delayed closure without osteotomy showed a continence rate of only 10%. There was another very revealing factor in this study. Bladder capacity at the time of bladder neck repair gave a strong indication not only of who would be dry but also who would be dry sooner. If the patients were

divided into those with a preoperative bladder capacity greater than or less than 100 mL, results showed that the group with the larger capacity had a high rate of continence: 42 of 50 dry and voiding versus 5 of 17 in the lower-capacity group. In addition, the mean times to dryness in the higher- and lower-capacity groups were 10 months and 21 months, respectively (14 months in the group overall).

In a similar series by [Purves and colleagues \(2008\)](#), the results in females mirrored those of the male group, with a slightly higher continence rate of 74% (dry day and night) and social continence again in 10%. Again, patients with capacity greater than 100 mL had better outcomes. In a phenomenon not seen in the males, 6 patients (20%) became continent after bladder and pelvic closure alone.

A continence procedure should be delayed until the bladder reaches a capacity of 100 mL and the child is motivated to be dry and participate in a postoperative voiding program. The vast majority achieve daytime dryness within 12 months after bladder neck repair. A few patients gain a longer daytime dry interval during the second year after their outlet procedure. However, patients who are not dry within 2 years are considered incontinent, and the procedure is considered to have failed. The onset of nighttime continence varies from 2 to 3 years and takes longer than the time needed for daytime continence. [Caione and colleagues \(1999\)](#) showed that use of desmopressin acetate (DDAVP) can increase the onset and number of dry nights in these patients. In the series by [Baird and colleagues \(2007\)](#), 25% of patients required either DDAVP or oxybutynin to establish nighttime dryness.

Urodynamic evaluation by [Dave and colleagues \(2001\)](#) showed that patients with good continence after bladder neck repair had high cystometric bladder capacity and compliance compared with those who were incontinent. However, unstable contractions were seen in both groups. Also, higher end filling pressures were reported, and those patients had a high incidence of nonobstructive hydronephrosis. These findings, in addition to those of [Bolduc and others \(2002\)](#), indicate that careful lifelong follow-up is essential in these patients after successful childhood reconstruction.

OTHER MODERN EXSTROPHY REPAIRS: CONTINENCE OUTCOMES

Warsaw Approach

The long-term reported outcomes of this repair include 36 patients with classic exstrophy and 37 with epispadias. Eighty-nine percent of patients with epispadias were continent during the day, but more than 40% were still wet at night. Seventy-five percent of patients with classic exstrophy had daytime continence, but nine had occasional wet nights. Eleven boys required short-term intermittent catheterization, which was easily performed by the patient and family. All but 2 began voiding within 3 to 5 months, and only 2 have continued with intermittent catheterization. Ureteral reimplantation was not performed at the time of bladder neck reconstruction and epispadias repair, but many patients required later reimplantation for gradually worsening hydronephrosis.

Compared with this experience, [Mathews and coauthors \(2003b\)](#) reported on a group of patients who had ureteral reimplantation performed at the time of bladder neck reconstruction and epispadias repair. None of these patients developed reflux or worsening hydronephrosis. [Baka-Jakubiak \(2000\)](#) recommends performance of this combined procedure if the bladder capacity is documented to be above 100 mL and the penis is large enough for epispadias repair. Follow-up urodynamic studies demonstrated the presence of normal detrusor function in most, although some patients developed high voiding pressures and some had poor detrusor contractility. If poor detrusor contractility was noted, prolonged intermittent catheterization was required and high voiding pressures were managed with anticholinergic therapy. Most patients were managed later in life, and the standard addition of ureteral reimplantation at the time of reconstruction should probably be universally performed.

Erlangen Approach

[Rosch and colleagues \(2001\)](#) have reported on 100 patients, using this technique in both newborns and failed closures. Ninety-one children with exstrophy (69 boys and 22 girls) and 9 with complete epispadias (7 boys and 2 girls) have had this procedure performed. The complete single-stage repair was performed in 47 children and included pelvic closure without osteotomy, bladder neck reconstruction, an antireflux procedure, and epispadias repair using the Cantwell-Ransley technique. An additional 53 patients underwent primary reconstruction elsewhere and then had bladder neck reconstruction and epispadias repair performed. Continence was defined as dryness for more than 3 hours and no nocturnal enuresis. Partial continence was defined as dryness for 1 to 3 hours, or for longer than 3 hours with occasional stress incontinence or wet nights. Patients dry for less than 1 hour were considered incontinent. Among the patients undergoing single-stage repair, 34 of 39 are dry (72%) and voiding per urethra, 2 of 39 are on clean intermittent catheterization (CIC), and 3 of 39 are on CIC after augmentation. Four patients are partially continent and 2 are dry on desmopressin. Four patients are incontinent and 3 have undergone continent diversion. Of 53 patients who underwent primary closure elsewhere, 55% are continent and 7 have been augmented. Fourteen are partially continent and 10 are incontinent, 4 of whom have undergone continent diversion.

Complete Repair

Various series have been published about outcomes, including the need for ureteral reimplantation in the first year of life, the number of patients requiring hypospadias repair after this procedure, and the complication rates of this procedure. However, little has been published about the long-term continence results or the need for bladder neck reconstruction in this group of patients. [Borer and colleagues \(2005\)](#) reported that ultimately almost 65% to 70% of patients undergoing CPRE in the newborn period will require a bladder outlet procedure. In an updated series, [Gargollo and colleagues \(2011\)](#) found that 80% of patients with long-term follow-up required bladder neck repair. In a series by [Hafez and colleagues \(2005\)](#) with some patients who had delayed or failed primary closures, 84% of males and 50% of females required bladder neck repair to be dry. Some of these required concomitant bladder augmentation to be dry. In another very large series by [Shoukry and colleagues \(2009\)](#), no patients were continent after CPRE alone and most required augmentation to be dry. More important, early dry intervals did not translate into later continence.

Mitchell and Grady (2008) reviewed their experience with 39 patients over 19 years with CPRE. Daytime voided continence was achieved in 74% of males and females with 4 years of follow-up. However, only 20% and 43% of boys and girls, respectively, achieved continence without the need for bladder neck repair. Eighteen percent achieved dryness with bladder neck injection only. In a recent series of CPRE patients referred for reclosure or after successful closure for bladder neck reconstruction, the results were very interesting ([Schaeffer et al, 2011](#)). All patients were operated on by an experienced senior surgeon who does not do CPRE in newborns. None of the 14 referred patients who underwent successful CPRE in the newborn period was continent for any appreciable interval after closure. Of the 19 patients who underwent bladder neck reconstruction after complications with their newborn closure, only 25% were voiding from the urethra and continent. In the group with a successful primary closure ($n = 14$), 57% were dry day and night and 28% were dry during the day only ([Schaeffer et al, 2011](#)). Of major interest, all patients who were dry after bladder neck reconstruction had a successful primary closure with pelvic osteotomy and hypospadias repair before 1 year of age, and none required ureteral reimplantation before bladder neck repair. These data clearly show that in the majority of cases "complete repair" patients will need to undergo bladder neck repair. However, as in all of the major repairs, a successful primary closure with fewer bladder violations and

interval surgeries will increase the chance for bladder growth and voided continence.

Other methods have combined epispadias repair with bladder exstrophy closure in the male patient. In a series of 38 boys with classic exstrophy, [Baird and colleagues \(2005c\)](#) evaluated patients with either failed or delayed primary closures. The complications were those seen with routine exstrophy repairs including urethrocutaneous fistula, urethral strictures, and so on. Three boys were dry with combined closure alone. Nineteen boys went on to modified Young-Dees-Leadbetter bladder neck repair. Twelve (63%) of these 19 were totally dry both day and night. These data as well as the data of Mitchell and Grady clearly show that epispadias repair and exstrophy closure can be combined with acceptable results. However, the complications are real and can portend the loss of any chance at volitional voiding, and the procedures should be performed only by experienced exstrophy surgeons and not the occasional surgeon.

Kelly Repair

There are not many papers with long-term follow up of the Kelly technique. However, a recent presentation by the Melbourne group gives the best and most current results that can be found with this repair ([Jarzebowski et al, 2009](#)). Data were collected in children older than 4 years. Complete continence was defined as dryness for longer than 3 hours day and night (with two or fewer wet nights per month). Partial continence was dryness for 2 or more hours during the day and 3 or more wet nights per month and/or stress incontinence. Twenty-four of 31 Kelly patients void spontaneously and 17 of 31 void in an unaided fashion (without intermittent catheterization or augmentation). Overall continence was 71%, with 3 of 17 (18%) voiding in an unaided fashion and having complete continence and 9 of 17 (53%) having partial continence. The 18% dry and voiding rate compares favorably to that recently reported for CPRE. Another study from Italy ([Berrettini et al, 2009](#)) showed that in 5 of 9 boys, continence was achieved with a Mainz pouch in 1, intermittent catheterization in 2, and by voiding in 2. One of 9 experienced glans loss ([Berrettini et al, 2009](#)).

EXSTROPHY RECONSTRUCTION FAILURES AND COMPLICATIONS

Failed Closure

After any form of repair, failures can manifest as complete bladder dehiscence, bladder prolapse, neourethral stricture and obstruction, soft-tissue loss, and vesicocutaneous fistula ([Massanyi et al, 2013](#)). [Meldrum and associates \(2005\)](#) reported on a select group of children in whom exstrophy reconstruction had failed before referral to a tertiary care facility. In the cohort of 101 children, 51 had primary surgical management performed by a fellowship-trained pediatric urologist, 18 by a general urologist, 6 by a pediatric surgeon, and 9 by an unknown surgeon. After successful reclosure, 38 patients eventually developed adequate bladder capacity for bladder neck reconstruction, and only 26% (10) eventually achieved dryness. These data emphasize the need for initial successful reconstruction and suggest that individuals undertaking this reconstruction should be comfortable with the complexity of repair. It is prudent for the surgeon who may see only a few patients with this condition to consider referral of these complex management situations to a center where special expertise and experience exist.

In a recent large series by [Schaeffer and colleagues \(2008\)](#), 185 patients who underwent closure by one of two surgeons were reviewed for both major and minor complications ([Table 139-3](#)). Sixty-three underwent osteotomy at the time of primary closure. There were 14 major complications (11%) and 27 minor complications (14%). Major urologic complications included bladder prolapse or dehiscence in 6 male patients (3%), all of whom underwent successful reclosure. Major orthopedic complications, including nonunion in two patients, leg-length inequality in 1, and persistent

TABLE 139-3 Urologic, Orthopedic, and Neurologic Complications in 185 Primary Bladder Closures

UROLOGIC COMPLICATIONS	NO.
Bladder prolapse and dehiscence	6
Postoutlet obstruction	4
Suprapubic tube removal	2
Intrapubic stitch erosion	4
Febrile urinary tract infection	6
Wound infection	3
Bladder calculi	5
ORTHOPEDIC COMPLICATIONS	
Nonunion osteotomy	2
Leg-length inequity	1
Persistent joint pain	1
Pelvic osteomyelitis	1
Pin site infection	3
Pressure sore	1
NEUROLOGIC COMPLICATION	
Femoral nerve palsy	4

joint pain in 1, developed in 4 of 63 patients (6%) who underwent osteotomy. Major neurologic complications included femoral nerve palsy in 4 of the 185 patients (2%). There were 21 minor urologic complications (11%) including posterior bladder outlet obstruction in 4 patients, urethrocutaneous fistula in 2, suprapubic tube removal in 2, intrapubic stitch erosion in 4, febrile UTI in 6, and surgical site infection in 3. Six patients (3%) had minor orthopedic complications including pelvic osteomyelitis in 1, pin site infection in 3, and a pressure sore from immobilization in 1.

Dehiscence, which may be precipitated by incomplete mobilization of the pelvic diaphragm and inadequate pelvic immobilization postoperatively, wound infection, abdominal distention, or urinary tube malfunction, necessitates a 4- to 6-month recovery period before a second attempt at closure can be made ([Gearhart and Jeffs, 1991a](#); [Gearhart et al, 1993b](#)) ([Fig. 139-25A1](#)). Dehiscence and prolapse after CPRE have also been reported and may be associated with glans, corporeal, urethral plate, and other major soft-tissue loss ([Fig. 139-25B and C](#)). Tension-free reclosure with osteotomy and immobilization are important factors in initial and subsequent closures. Unfortunately, the chance of obtaining adequate bladder capacity for bladder neck plasty and eventual continence after multiple closures is markedly diminished ([Gearhart et al, 1996a](#); [Novak et al, 2010](#)). Similarly, bladder prolapse is considered a failure and requires bladder reclosure or revision. In a recent series from a single institution of 122 patients who underwent reclosure with a mean follow-up of 14 years, the voided continence rate was 16% ([Novak et al, 2010](#)). In a patient with significant bladder prolapse or dehiscence, at the time of secondary closure we combine epispadias repair with bladder, posterior urethral, and abdominal wall closure ([Gearhart et al, 1998](#)). The patient is given testosterone enanthate intramuscularly 5 weeks and 2 weeks before surgical repair and undergoes an osteotomy with concomitant bladder, urethral, and abdominal wall closure. Major soft-tissue loss that is seen after CPRE necessitates extensive preoperative planning; use of buccal mucosal or full-thickness grafts and tissue expansion may be required before definitive surgery ([Gearhart and Baird, 2005](#)).

[Baird and coauthors \(2005c\)](#) reported on 38 boys undergoing combined exstrophy closure and epispadias repair along with osteotomy; in 30, prior reconstruction had failed. Complications in this group were limited to urethrocutaneous fistulae and urethral strictures. Although the results after reclosure are not as good as those obtained with a successful primary closure, they are respectable and may obviate the need for bladder augmentation.

Figure 139-25. A1, Failed female newborn closure. A2, Major bladder prolapse after complete primary repair of exstrophy (CPRE) without osteotomy. B, Complete dehiscence and loss of right glans and partial loss of corpora after CPRE. C, Loss of right glans and urethra after penile disassembly in newborn (under testosterone stimulation before placement of full-thickness skin graft).

Neourethral stricture is often associated with paraexstrophy skin flap use, pubic suture reaction, erosion, or the use of urethral stents. This may be somewhat subtle; however, warning signs consist of UTIs, detectable increased bladder volumes on ultrasonography, bladder stones, prolonged dry intervals, and unexplained rectal prolapse. In a review by [Baker and colleagues \(1999\)](#), posterior urethral obstruction was found in 41 patients. Most episodes occurred within 60 days after primary closure. If diversion was used for longer than 6 months, the ultimate fate of the bladder was augmentation. If diversion was used for less than 6 months, most reconstructions were ultimately bowel free. The authors have also seen outlet obstruction including complete obliteration after both the CPRE and Kelly repair ([Hernandez et al, 2008](#)). Whether this is a result of ischemic damage to the urethral plate or technical error is unclear. Regardless, because there is a paucity of long-term data from these two repairs, the outlet must be monitored carefully as with all exstrophy patients after primary closure. Ultimately, posterior urethral obstruction after exstrophy closure markedly decreases

the success of any repair. This complication presents a significant risk to the upper urinary tract and should be detected early.

Although all closed exstrophy bladders have vesicoureteral reflux, upper tract deterioration is the ultimate fate of significant outlet obstruction. At this point the management includes urethral dilation (incision), open urethroplasty, or upper tract diversion. If renal function is compromised, the choice must achieve unquestionable free drainage to allow the upper tracts and kidneys to recover fully. Further bladder neck or urethral reconstruction should not be performed until the posterior urethral stricture is clearly repaired and free drainage has been achieved. After CPRE repair, up to 50% of patients will require bilateral ureteral reimplantation during the first year after surgery because of UTIs and increasing hydronephrosis.

[Massanyi and colleagues \(2012\)](#) found that a high number of patients with a vesicocutaneous fistula after primary closure actually have a failed closure. On evaluation 13 of 18 patients referred because of vesicocutaneous fistulae were found to have a failed closure

represented by (1) a fistulous tract in the lower abdominal midline; (2) a pubic diastasis increased from preclosure measurements; and (3) cystoscopic evidence of an anteriorly positioned bladder just under the abdominal skin.

Despite satisfactory closure, some bladders never achieve adequate capacity to act as functional bladders. [Baradaran and colleagues \(2011\)](#) presented a large series of patients including those with failed primary bladder closures ($n = 62$) who underwent successful secondary closure; these patients were evaluated and compared with another group of patients with successful primary closures ($n = 48$). Both groups were followed over 5 years. Bladders in patients who had had a successful primary closure had a significantly larger cystographic capacity than the group with failed closure. Bladders grew at a significantly slower rate in the group with failed procedures and had significantly lower bladder capacities over time. These data underscore the importance of a successful primary closure. It has become clear that multiple bladder closures, bladder prolapse, dehiscence, bladder calculi, recurrent infections, and vesicostomy have a negative impact on the potential of the exstrophy bladder ([Silver et al, 1997b](#)).

Unsuccessful primary closures regardless of the method of repair really calls into question the ability of the bladder to grow, undergo an eventual bladder neck reconstruction, and be continent of urine. [Schaeffer and colleagues \(2011\)](#) reported on a large series of patients with failed CPRE procedures who were referred for further treatment. Of the 23 male patients, only half obtained a capacity sufficient for a bladder neck procedure, and only 25% were voiding and continent. [Novak and colleagues \(2010\)](#) reported a very large series of 122 patients with a failed primary or secondary closure of whom 94 underwent a successful repeat closure. Only 38 were candidates for bladder neck repair and only 17 of the 94 (18%) were voiding and continent. Thus, regardless of the type of repair, a failed closure portends significant implications for long-term surgical outcomes.

We have used transurethral injection of collagen and dextranomer around the bladder neck to increase outlet resistance and stimulate the bladder to grow. However, in our hands this has not been as successful as reported by [Caione and colleagues \(1993a, 1993b\)](#). If the bladder does not grow to a sufficient size for bladder neck reconstruction, bladder augmentation is recommended in this situation. If the bladder neck or urethra or both are problematic, a catheterizable continent stoma with or without bladder neck plasty or transection is performed, along with augmentation ([Gearhart et al, 1995b](#)).

Failed Bladder Neck Repair

Even with experienced exstrophy surgeons, missteps can occur, and there remains a subgroup of children with urinary incontinence after bladder neck reconstruction secondary to (1) inadequate outlet resistance; (2) a small bladder capacity (lack of growth after bladder neck reconstruction); (3) decreased compliance; or (4) a combination of these factors.

If urinary continence, defined as a 3-hour dry interval, is not achieved within 2 years after bladder neck reconstruction, failure to achieve dryness has resulted. Occasionally the dry interval is nearly acceptable for daytime dryness (i.e., longer than 2 hours). In these situations urethral bulking agents have been used in an attempt to avoid further major reconstructive procedures ([Burki et al, 2006](#)). Formerly, collagen was the bulking agent of choice, but often multiple injections were required ([Ben-Chaim et al, 1995a](#)). In a large series from Paris, [Lottmann and colleagues \(2006\)](#) reported on the use of a dextranomer-based bulking agent in childhood with incontinence from multiple causes. Twenty-six patients had the exstrophy-epispadias syndrome. Of the 9 exstrophy patients, 4 achieved success; in the epispadias group the success rate was much higher (longer than 3 hours dry by intermittent catheterization or voiding).

In a recent very large series of specifically exstrophy-epispadias patients ([Shah et al, 2014](#)) with a median follow-up of 8 years, 41 underwent injection before bladder neck reconstruction and 25 after bladder neck reconstruction. Injection before bladder neck

reconstruction did result in 50% developing an adequate capacity for bladder neck reconstruction, but only 9 (22%) became dry. Bladder capacity was the most predictive variable of a successful bladder neck reconstruction after bladder neck injection. In the group of 25 patients with prior bladder neck surgery of whom 16 were partially dry (1 to 3 hours), all were rendered socially continent (dry for longer than 3 hours) after bladder neck injection. Of the 9 dry for less than 1 hour, bladder neck injection was not helpful at all. Thus, outlet injection after a failed bladder surgery is more successful if a reasonable dry interval has been achieved with open bladder neck surgery. In recent data from [Alova and colleagues \(2012\)](#), bladder neck surgery after prior dextranomer bladder neck injection was not found to be more difficult and success rates were quite acceptable with long-term follow-up. However, repeated dextranomer injections after a prior failure did not result in success.

Some successes have been seen with repeated Young-Dees-Leadbetter repair if the bladder neck is patulous, the bladder capacity is adequate, and urodynamic evaluation reveals a stable bladder ([Gearhart et al, 1991](#)). In that series only 50% of patients with a failed prior bladder neck reconstruction were candidates for reoperative surgery. In this highly select group, continence rates were acceptable after reoperative bladder neck reconstruction. All of these patients had excellent bladder capacity (>100 mL) and were stable on urodynamics before the redo repair. A majority of bladder neck failures require eventual augmentation or continent diversion ([Burki et al, 2006](#)). The artificial urinary sphincter has been used with some success in patients who have a good bladder capacity. However, in most of these failures the bladder capacity is small and augmentation is required. At the time of reoperative surgery, either the bladder neck is transected proximal to the prostate with a Mitrofanoff substitution or a continence procedure, such as creation of an artificial sphincter, is performed. In our extensive experience with failed bladder neck reconstructions, most of the patients have had several surgeries of the bladder neck area and are desperate to be dry. In a recent large series of 31 patients who had undergone prior bladder neck reconstruction, [Novak and colleagues \(2009\)](#) found that most patients had undergone multiple prior repairs to achieve continence. Bladder neck transection along with enterocystoplasty was performed with initial continence achieved in 86%. Seven patients underwent further bladder neck surgery, and 90% achieved dryness by intermittent catheterization. One renal unit was lost, nonobstructive hydronephrosis developed in 8, and bladder stones occurred in 30%.

Delayed urinary continence has been reported at the onset of puberty in some males, and this has been attributed to prostatic growth. On MRI, the prostate of exstrophy patients is cloverleaf shaped and absent anteriorly, and its mean weight and maximal cross section and volume are normal ([Gearhart et al, 1992](#)). Therefore, it is doubtful that growth of this abnormally configured prostate can have much impact on urinary continence after failed bladder neck repair, and improved continence at puberty may be a result of changes in the pelvic floor with maturity.

Failed Genitourethral Reconstruction

Common complications of modern epispadias repair include urethrocutaneous fistula formation. This has been reported in as few as 4% and as many as 19% of cases ([Kajbafzadeh et al, 1995](#); [Surer et al, 2000](#)). Urethral tortuosity with difficult catheterization or strictures are uncommon with modern epispadias repair. Since the application of the penile disassembly for epispadias reconstruction, newer, more significant complications have been noted ([Hammouda, 2003](#)). [Gearhart and Baird \(2005\)](#) have reported loss of the glans, corpora, or both in addition to loss of penile skin and the urethral plate (see [Fig. 139-25C](#)). Whether this is secondary to surgical misadventure, vagaries in the blood supply of the penis, or the intrinsic difficulties in the procedure remains a topic of debate. Reconstruction of these complications has required additional techniques including tissue expansion, full-thickness skin grafting, buccal mucosal grafting, and other complex techniques. In some patients with significant losses, neophalloplasty may eventually provide the

material for final cosmetic reconstruction. Recent data by [Massanyi and colleagues \(2012\)](#) shows the applicability of radial forearm phalloplasty in patients who have lost glans, corpora, and other soft tissue as a consequence of epispadias repair or in cloacal exstrophies where penile tissue hardly exists. This alternative allows a sensate cosmetic neophallus for this special group of exstrophy failures.

At an older age, unsightly penile scars and a short phallus may prompt further surgical intervention. Scar excision can be closed in a plastic fashion if enough penile skin is available. Otherwise, flaps or full-thickness skin grafts can be used. In severe cases, tissue expanders can be placed under the penile skin and gradually inflated over 6 weeks to allow more penile skin and obviate the need for grafting. Freeing all scar tissues and suspensory ligament tissue can maximize available penile length. A dorsal dermal corporeal graft or ventral corporeal plication or rotation may also help lengthen as well as correct any chordee. However, it must be recognized that the exstrophy penis, when compared with age- and race-matched controls, is congenitally deficient in anterior corporeal tissue as assessed by MRI ([Silver et al, 1997b](#)). Therefore, overly aggressive attempts at penile lengthening may result only in corporeal denervation and devascularization without additional lengthening.

Alternative Techniques of Reconstruction

Not all children with bladder exstrophy are candidates for primary repair at initial evaluation because of a small bladder plate or significant hydronephrosis. Additional reasons for seeking other methods of treatment include failure of initial closure with a small remaining bladder or failure of continence surgery, or both. Excluding the patients in whom initial treatment fails, this discussion deals with options available when modern repair is not chosen by the surgeon or for other reasons has not been suitable.

Ureterosigmoidostomy

Whichever urinary diversion is chosen, the upper tracts and renal function are initially normal. This allows the reimplantation of normal-sized ureters in a reliable, nonrefluxing manner into the colon or other suitable reservoir. Historically, ureterosigmoidostomy was the first form of diversion to be popularized for patients with exstrophy. Although the initial series was associated with multiple metabolic problems, results improved markedly with newer techniques of reimplantation ([Zarbo and Kay, 1986](#); [Koo et al, 1996](#)). Ureterosigmoidostomy is favored by some because of the lack of an abdominal stoma. **However, this form of diversion should not be offered until one is certain that anal continence is normal and after the family has been made aware of the potential serious complications, including pyelonephritis, hyperkalemic acidosis, rectal incontinence, ureteral obstruction, and delayed development of malignancy** ([Spence et al, 1979](#); [Duckett and Gazak, 1983](#)). More recently, ureterosigmoidostomy has been proposed again as an initial treatment of bladder exstrophy with acceptable continence and renal preservation on follow-up of 10 years or longer. In a long-term Swiss study by [Gobet and colleagues \(2009\)](#) of 42 patients, 50% had their ureterosigmoidostomy in place and were fecally continent at 50 years of age. One had developed a colonic malignancy and 60% had normal renal function. Another good-sized study from Sweden by [Pettersson and colleagues \(2013\)](#) found a higher rate of colorectal cancer than the Swiss study and a higher rate of rediversion. The mean time from ureterosigmoidostomy was 38 years. Almost all of the malignancies were poorly differentiated adenocarcinoma. The difference in the results of these two European studies is unclear but underscores the need for lifelong vigilance for early detection of cancer.

[Stein and associates \(1999\)](#) treated a group of 128 patients with bladder exstrophy-epispadias with the Mainz technique for ureterosigmoidostomy. The Mainz Sigma pouch is constructed and the ureters reimplanted in a nonrefluxing manner. The abdominal wall is reconstructed and the bladder is closed as a seminal receptacle above the prostate. The penis is then reconstructed at a later date. [D'elia and coauthors \(2004\)](#) reported on 26 patients with the

exstrophy-epispadias complex who showed excellent continence rates with long-term upper tract preservation when compared with standard ureterosigmoidostomy. Continence was achieved in 95% of patients with a rectal reservoir. Their recommendation for treatment in a number of patients with severely impaired renal function was that a colonic conduit was the best method of choice for diversion. In the patients with a normal or slightly dilated upper tract and intact anal sphincters, a Mainz rectal reservoir was recommended. Although the group from Mainz reported no cancer in a long-term follow-up study of patients who underwent ureterosigmoidostomy, the risk for malignancy still exists. Patients who have had mixing of urine and feces at any time during reconstruction remain at high risk for the development of cancers ([Smeulders and Woodhouse, 2001](#)). Bladder exstrophy patients in whom an initial reconstruction has failed and who have polyposis at the time of repeated closure may also be at higher risk for the later development of malignancy ([Novak et al, 2005](#)). This is especially true in today's very mobile society, in which careful long-term follow-up may be difficult to guarantee. All patients with a ureterosigmoidostomy should have a yearly renal ultrasound and colonoscopy in adult life.

Continent Urinary Diversion in the Exstrophy Patient

In modern pediatric urology there is usually very little need for incontinent urinary diversion in the patient with bladder exstrophy. In a young child with a bladder that is too small to close, or in a failed closure where the bladder template is too small to reclose, we recommend a nonrefluxing colon conduit. This protects the kidneys from vesicoureteral reflux, and undiversion can be performed when clinically indicated at an older age.

Advances in the reconstruction of the lower urinary tract in the past several years have been applied to the patient with exstrophy. ([Cervellione et al, 2008](#)). Most commonly, further reconstruction is required in the patient in whom bladder neck reconstruction has failed. If a patient does not meet the criteria for bladder neck reconstruction (i.e., inadequate bladder capacity or inability to conform to a voiding regimen), deferring surgery is advisable. Patients in whom bladder neck reconstruction fails are most often destined to augmentation cystoplasty and continent urinary diversion. [Surer and colleagues \(2003\)](#) reported on 91 patients with the exstrophy-epispadias complex who underwent continent urinary diversion. The majority had undergone prior failed bladder neck reconstruction (n = 62). Seventy-nine patients (87%) had exstrophy closure before referral, 53 had also undergone bladder neck reconstruction, and 29 patients had never reached adequate capacity for bladder neck reconstruction. Ten of the 53 patients had undergone one prior attempt, 35 had undergone two prior attempts, and 8 had undergone three prior attempts at bladder neck reconstruction. A combined augmentation cystoplasty, continent urinary diversion, and bladder neck closure was performed in 59 patients (65%), and reaugmentation and continent urinary diversion was performed in 18 children. Ileocystoplasty was used in 41 patients, and sigmoid cystoplasty was performed in 30 patients. The appendix was used as the continent channel in 67 patients. Continence using intermittent catheterization through the stoma was achieved in 93% of children with the most common complication reported being that of bladder stones, noted in 26%. Although infrequent, failures can occur with continent urinary diversion in exstrophy ([Frimberger et al, 2003](#)). The most common modes of failure were a detrusor intussusception of a nipple valve, inadequate tunnel for an appendiceal channel, or continued bladder neck incompetence. The vast majority of these complications can be successfully repaired. Equally successful outcomes have been reported by [Baird and colleagues \(2005a\)](#) in adolescents who had undergone a mean of eight prior procedures before their definitive repair.

Occasionally, urinary diversion must be established at a very young age (5 years or younger). The need for early diversion in exstrophy is mainly driven by upper tract changes and social factors and can be safe in younger children with a favorable continence outcome. In a recent offering by [Baradaran and colleagues \(2012b\)](#), 19 patients underwent early diversion (14 continent, 5 incontinent).

Of the group who underwent early continent diversion, 7 had an early desire to be dry; 4 had persistent severe hydronephrosis; 1 had severe recurrent pyelonephritis; 1 underwent a repeat continent urinary diversion; 1 had inaccessible proper follow-up; and only 2 had a successful primary closure. Three patients had neobladder creation, 10 had augmentation with a continent stoma, and 2 had ureterosigmoidostomy. Currently, all patients with stomas are dry on intermittent catheterization. Continence can be achieved in most patients with exstrophy after failure of bladder neck reconstruction and is typically obtained through augmentation cystoplasty and closure of the bladder neck. If a patient is unlikely to develop adequate capacity for eventual bladder neck reconstruction, moving early to continent urinary diversion is preferable. One long-term concern has been the risk of malignancy in patients with continent urinary diversion. Recent data by [Husmann and Rathbun \(2008\)](#) revealed that the overall rate of malignancy is low unless associated with coexisting carcinogenic stimuli (prolonged tobacco, chronic immunosuppression) or the inherent risk associated with bladder exstrophy.

ADOLESCENTS AND ADULTS WITH EXSTROPHY-EPISPADIAS COMPLEX

As children with exstrophy grow into adulthood, there is an increasing need to address long-term functional and psychological aspects of dealing with a multiorgan birth defect. Some aspects such as sexuality and continence are common to all forms of the exstrophy-epispadias complex; however, in cloacal exstrophy there are additional neurologic and orthopedic aspects that can lead to significant disability.

A mainstay of the functional reconstruction of the exstrophy-epispadias complex is the preservation of renal function. Functional reconstruction of the exstrophy-epispadias complex has been associated with good preservation of renal function ([DeMaria et al, 1980](#); [Schaeffer et al, 2013](#)). Renal function, however, can be compromised after urinary diversion ([Husmann et al, 1988](#)). Although urinary diversion has been used successfully as a temporary modality for providing upper tract decompression ([Baradaran et al, 2012b](#)), most children will eventually undergo undiversion to continent urinary pouches. Long-term urinary diversion is now infrequently used in the exstrophy-epispadias complex.

CONTINENCE

Early surgical management of patients with bladder exstrophy included initial cystectomy and replacement with an ileal conduit or ureterosigmoidostomy. The use of ureterosigmoidostomy has fallen into disfavor owing to an increased identification of lethal colonic cancer ([Gobet et al, 2009](#)). Renal function, however, was preserved in the majority of patients with ureterosigmoidostomy. Some institutions have been using continent catheterizable pouches for bladder management ([Nerli et al, 2008](#)). More recently, however, use of augmentation cystoplasty with bladder neck reconstruction or closure has been used successfully to provide continence in the majority of patients ([Novak et al, 2009](#); [Kavanagh et al, 2012](#)). Long-term concerns about augmentation cystoplasty continue to be raised. [Fontaine and colleagues \(2000\)](#) evaluated 53 patients who had undergone augmentation cystoplasty and had at least 10 years of follow-up. In 80% of patients, there was no reduction in GFR noted. Remediable causes were found to account for the reduction in GFR noted in the remaining 20% of patients, leading the researchers to conclude that augmentation cystoplasty was effective in providing urine storage without compromising long-term renal function. Owing to the long-term potential for carcinogenesis in patients who had undergone ureterosigmoidostomy, concerns were raised regarding tumor formation in children with augmentation cystoplasty. [Husmann and Rathbun \(2008\)](#) reviewed their experience with 153 patients who had undergone augmentation cystoplasty; 38 of these patients had bladder exstrophy, of whom 3

developed multifocal adenocarcinoma, which suggests that there may be an inherent risk for long-term carcinogenesis in patients with bladder exstrophy who undergo augmentation. Exposure to cigarette smoking increased the potential for the development of cancers in patients with augmentation cystoplasty, as did the use of immunosuppression for post-transplant management. Endoscopic surveillance beginning 5 years after reconstruction has been suggested; however, identification of early lesions can be difficult in the augmented bladder. Fecal incontinence has recently been noted in patients with bladder exstrophy and appears to persist into adulthood ([El-Hout et al, 2010](#)). Although this has not been noted by other investigators, ongoing evaluation for this psychologically debilitating problem seems appropriate.

SEXUALITY

Male Concerns

The most often expressed male concerns relate to the length, appearance, and the axis deviation (chordee) of the penis noted with exstrophy. Functional penile length can be gained by degloving the penis and resecting all of the residual scar tissue and releasing any remnants of the suspensory ligaments. Skin coverage can be a significant problem after penile lengthening procedures. Use of tissue expansion will permit local skin to be used for coverage; however, this will require preplanning. Placement of a tissue expander and subsequent expansion can take 4 to 6 weeks. If the penile skin is not ideal for expansion, full-thickness grafting is a suitable alternative ([Hernandez et al, 2008](#)). Residual dorsal chordee from childhood reconstruction is not uncommon. Grafts (dermal grafts, tunica vaginalis, human AlloDerm) can be used to lengthen the dorsal aspect of the penis. Our preference is human AlloDerm because it is readily available, durable, and easy to use. Because of its anatomy, the penis must be opened dorsally for one half of its circumference as described by [Perovic and Djinic \(2008\)](#) to both lengthen and straighten the penis. Early measurements and determinations from artificial erections must be adequate because after grafting, the artificial erections can leak saline through the suture lines and give misleading information about the adequacy of correction.

In the cloacal exstrophy patient, the corporeal structures can be very small, and the only option for a functional phallus would be reconstruction with flap phalloplasty (see earlier). Retention of all of the present corporeal and glanular tissue will permit a location for anchorage of the neophallus ([Ballaro et al, 1999](#)).

Sexual function and libido in exstrophy patients are normal ([Woodhouse, 1998](#)). The erectile mechanism in patients who have undergone epispadias repair appears to be intact because 87% of boys and young men in the Hopkins series experienced erections after repair of epispadias ([Surer et al, 2000](#)). [Woodhouse \(1998\)](#), [Ben-Chaim and colleagues \(1996\)](#), and [Ebert and coworkers \(2008\)](#) reported satisfactory orgasmic function in most patients. In the men who had participated in sexual intercourse, female partners also expressed sexual satisfaction. In the series by Ben-Chaim, the only patients who had no ejaculation were 2 patients who had undergone cystectomy. A report from Castagnetti and colleagues (2010) of 19 men with bladder exstrophy evaluated via the International Index of Erectile Function questionnaire and compared with normal men indicated a higher incidence of erectile dysfunction (58%) as compared with the normal controls (23%). Erectile function was worse in those who had undergone multiple surgeries for treatment of incontinence. Orgasmic function was also noted to be lower in men with exstrophy. It is interesting to note that no difference in sexual desire, sexual satisfaction, or overall satisfaction was indicated, leading the authors to conclude that men with bladder exstrophy seem to lead a sexual life that is as satisfactory as that of their peers. Overall, it seems from the reports of many investigators that most men with exstrophy are able to achieve normal erectile function and are sexually satisfied.

As men grow into adulthood, additional concerns are now becoming evident and require transition of care to adult urology

specialists. Men with bladder exstrophy will increasingly be seeking evaluation for prostatic hyperplasia and prostate cancer (Berkowitz et al, 2008). Silver and colleagues (1997a) reported on the ability to identify PSA in men with exstrophy. PSA was noted to be below the upper age-specific limit of norms, indicating that PSA changes could be muted in men with exstrophy. Routine digital rectal examination and PSA screening should become part of the standard follow-up for men with bladder exstrophy as with age-related screenings for normal men.

Female Concerns

The three main female concerns are the appearance of the external genitalia, adequacy of the vaginal opening, and uterine prolapse. Although initial correction of the female external genitalia defect is performed at birth, sometimes “touch-up” surgery needs to be performed at puberty. The appearance of the external genitalia is compromised owing to the recurrence of the pubic diastasis, which leads to widening of the inferior abdominal scar and separation of the pubic hair. In addition, separation of the clitoral halves may be noted. To repair this in adolescence, mons flaps are raised laterally and brought to the midline and sewn to the fascia and themselves easily. In extreme cases with an extremely scarred flat mons veneris, tissue expanders can be placed laterally and gradually inflated over 6 weeks. These flaps are moved medially and used to reconstruct the mons. The pseudocapsules are rolled together in the midline to give the mons a more elevated appearance. Mobilizing lateral mons veneris flaps brings the clitoral halves closer to the midline and makes them easier to reconstruct into a single entity. Topical estrogen cream is used three times daily for 2 weeks before any external genital surgery to soften scars, increase skin viability, and improve local vascularity. The vaginal orifice is more vertical and somewhat stenotic in exstrophy compared with normal females (Cervellione et al, 2010). Insertion of tampons and sexual intercourse can therefore be difficult. Rotating an inverted U-flap of perineal skin into the incised posterior vaginal wall will permit widening of the vaginal os (Stein et al, 1995). Uterine prolapse may be noted more frequently in women who have had vaginal wall cutback (Mathews et al, 2003a). After vaginal reconstruction, if the patient is not sexually active a vaginal dilator is used once daily until sexual activity occurs.

Uterine prolapse has been noted more frequently and at younger ages in girls with exstrophy-epispadias complex (Mathews et al, 2003a). Woodhouse (1999) reported prolapse in a number of patients, and it is a considerable problem to correct. Seven patients had total prolapse, one of whom had never had intercourse or a pregnancy. Woodhouse believes that prolapse may occur in up to half of patients after pregnancy. In a report from Mathews and coauthors (2003a), vaginal and uterine prolapse was noted commonly and even quite early in life (mean age 16 years). Uterine suspension provided only modest success for the prevention of recurrent prolapse. Stein and colleagues (1995), in a large exstrophy series from Germany, found that uterine fixation was required to correct prolapse in 13 patients with long-term follow-up of more than 25 years. The anterior displacement of the vaginal os and the marked posterior displacement of the puborectalis sling with its deficient anterior component were postulated as reasons for prolapse. Use of osteotomy has not been shown to reduce the incidence of uterine prolapse; however, the degree of pubic diastasis has been shown to be significant (Anusionwu et al, 2012). The degree of prolapse depends on the degree of pubic bone divergence and the diameter of the opening in the levator hiatus for the vagina and rectum (Miles-Thomas et al, 2006). We suspend the uterus to the sacrum with human AlloDerm or Pelvicol pubovaginal sling. The suspensory substance is sewn to the uterus from the cervix and dome of the uterus so that it can be snugly suspended to the ligaments on the front of the uterus. Regardless of the method of repair, the uterus must be anchored in such a way that it is fixated in the pelvis and less susceptible to prolapse.

Prophylactic suspension of the uterus in adolescent girls with exstrophy undergoing urinary reconstruction should be considered

to prevent prolapse (Stein et al, 1999). Woodhouse (1999) believed that although prophylactic surgery may be helpful, once prolapse occurs, anterior fixation is insufficient to correct uterine prolapse in the exstrophy patient. Woodhouse recommends fixing both sides of the uterus from the cervix to the top of the uterus bilaterally to the presacral ligaments.

Mathews and coauthors (2003a) reported on a large series of girls and women with the exstrophy complex. All girls older than 18 years indicated that they had normal sexual desire, and many were sexually active. Mean age for commencement of sexual activity was 19.9 years. Although a few patients complained of dyspareunia, most indicated normal orgasms. Some patients indicated that they restricted sexual activity because of the cosmetic appearance of their external genitalia. Mons plasty is therefore very important to obtain a cosmetically pleasing appearance either in infancy or in adolescence because hair-bearing skin and fat should be used to cover the midline defect. As mentioned earlier, we perform this procedure at the time of initial closure. It certainly can be done in adolescence with the use of rhomboid flaps, as popularized by Kramer and colleagues (1986).

FERTILITY

The Male Patient

Reconstruction of the male genitalia and preservation of fertility were not primary objectives in early surgical management of bladder exstrophy. Sporadic instances of pregnancy or the initiation of pregnancy by males with bladder exstrophy have been reported. In two large exstrophy series, male fertility was documented. Only 3 of 68 men in one study (Bennett, 1973) and 4 of 72 in another (Woodhouse et al, 1983) had successfully fathered children. Milking the urethra in an antegrade fashion from proximal to distal has provided pregnancy in some cases (Woodhouse, 1999). In a large series of 2500 patients with exstrophy and epispadias (Shapiro et al, 1985), there were 38 males who had fathered children.

Hanna and Williams (1972) compared semen analyses in men who had undergone primary closure and ureterosigmoidostomy. A normal sperm count was found in only 1 of 8 men after functional closure and in 4 of 8 men with diversion. The difference in observed fertility potential is probably attributable to iatrogenic injury to the verumontanum during functional closure or bladder neck reconstruction. Retrograde ejaculation may also account for low sperm counts after functional bladder closure. In a long-term study from our institution, Ben-Chaim and associates (1996) found that 10 of 16 men reported they ejaculated a few cubic centimeters of volume, 3 ejaculated only a few drops, and 3 had no ejaculation. Semen analysis was obtained in 4 patients: 3 had azoospermia and 1 had oligospermia. The average ejaculated volume of the patients who had sperm counts was 0.4 mL. In another large series by Stein and colleagues (1994) from Germany, the authors found that none of the patients who had reconstruction of the external genitalia could ejaculate normally, nor had they fathered children. Five patients who did not undergo reconstruction had normal ejaculation, and 2 had fathered children. The conclusion was that male patients with genital reconstruction and closure of the urethra demonstrated high risk of infertility. In a large study of successful primary closure from a large exstrophy center by Ebert and colleagues (2008), sperm parameters were poor in 18 of 21 patients and follicle-stimulating hormone was increased in 25% of patients (Ebert et al, 2009). Ebert and colleagues (2010) reported on 17 adult men with bladder exstrophy undergoing the Erlangen approach single-stage procedure. At a mean follow-up of 19 years, 15 had bladder preservation and 12 were voiding per urethra. 16 men had proven ejaculation and 3 had normal sperm counts, 7 had oligoasthenospermia, and 6 had azoospermia. The potential for normal sperm counts was greater in patients who underwent only a single bladder neck procedure.

Assisted reproductive techniques have been applied to the exstrophy population (D'Hauwers et al, 2008). Regardless of the

method of reconstruction of the external genitalia and bladder neck, newer techniques such as gamete intrafallopian transfer (GIFT) or intracytoplasmic sperm injection (ICSI) can be used to assist these patients in their goal of achieving pregnancy. Use of GIFT or ICSI in 21 men with exstrophy led to successful pregnancy with no instances of exstrophy in any of the offspring.

The Female Patient

Krisiloff and colleagues (1978) reported on 45 women with bladder exstrophy who successfully delivered 49 normal offspring. The main complication after pregnancy was cervical and uterine prolapse, which occurred frequently. Burbage and coworkers (1986) described 40 women ranging from 19 to 36 years of age who were treated in infancy for bladder exstrophy; 14 pregnancies in 11 of these women resulted in 9 normal deliveries, 3 spontaneous abortions, and 2 elective abortions. Uterine prolapse occurred in 7 of the 11 patients during pregnancy. All had undergone prior permanent urinary diversions. Spontaneous vaginal deliveries were performed in those women, and cesarean sections were performed in women with functional bladder closures to eliminate stress on the pelvic floor and to avoid traumatic injury to the urinary sphincter mechanism (Krisiloff et al, 1978). With modern reconstructive techniques, successful pregnancies have been reported in female patients who have undergone continent urinary diversion (Kennedy et al, 1993). Giron and colleagues (2011) reported on 14 women who had undergone successful reconstruction and had 22 pregnancies. Seventeen pregnancies resulted in healthy newborns, 1 premature delivery of an infant who did well, 4 spontaneous abortions caused by genital prolapse, and 1 postpartum demise. After delivery, 3 mothers had temporary urinary incontinence, 1 mother had a vesicocutaneous fistula, and 7 women (50%) had genital prolapse. In a larger report on 52 women with bladder exstrophy, Deans and colleagues (2012) reported on reproductive outcomes. Of those who attempted conception, 66% were successful; 19 patients conceived and there were 3 sets of twins—a total of 57 pregnancies. There were 34 of 57 live births (56%), 21 of 57 miscarriages (35%), 1 termination, and 4 stillbirths. There were 4 major complications related to delivery including 1 ureteral transection, 1 fistula formation, and 2 postpartum hemorrhages. Deans and colleagues (2012) stress that pregnancy in women with bladder exstrophy remains high risk for both the mother and the fetus and stress the need for referral to a tertiary care center for successful outcomes. In the majority of cases, planned cesarean section appears to be the safest mode for delivery.

QUALITY OF LIFE

Overall and health-related quality of life (QoL) have become increasingly important as reconstructive techniques have improved and survival has become universal. Most groups have limited their studies to those with CBE. The preliminary results of the QUALEX (Quality of Life of Bladder Exstrophy) study (Jochault-Ritz et al, 2010) suggest that after reconstruction patients had reduced QoL. Adolescents reported a superior QoL score as compared with adults and children. Another report from Wittmeyer and colleagues (2010) of 47 patients (9 women and 16 men) also showed that QoL scores were less than norms; however, these reductions were mainly based on health concepts including limitation of physical activity and general health perception. Dodson and colleagues (2010) reported that overall adolescent QoL was comparable to norms, but parents reported significantly impaired adolescent general health and family activity and increased parental emotional distress. Schaeffer and colleagues (2013) confirmed that adolescents with bladder exstrophy appear to have good QoL scores when compared with norms; although incontinent patients had a tendency to have lower QoL scores, the sample size evaluated was inadequate to demonstrate statistical significance.

LONG-TERM ADJUSTMENT ISSUES

Interest has increased in long-term adjustment issues in patients with bladder exstrophy. Children with exstrophy undergo multiple reconstructive surgeries and have potential problems with respect to urinary incontinence and sexual dysfunction. However, the ultimate outcome would be better measured by how these children adjust overall in society. The severe nature of the exstrophy disorder could predict that this birth defect could have substantial psychological implications. Parental reaction to the child's medical condition may change the way the parents interact with the child. Incontinence may have a negative impact on social function and self-esteem. Multiple hospitalizations may interfere with the ability to be like other children. Concerning the potential medical and psychological implications of this anomaly, children born with exstrophy may be at increased risk for difficulties.

Formerly, there was a limited amount of information in the literature concerning this condition and its treatment and whether or not it has a deleterious effect on children and their families. Montagnino and coworkers (1998) evaluated younger children who performed more poorly and had disturbed behavior, specifically in skills related to function in school. Children who achieved continence after the age of 5 years were more likely to have problems with acting-out behavior. There were no differences in adjustment based on male or female sex, bladder versus cloacal exstrophy, type of continence strategy, or gender reassignment versus no reassignment. The conclusions of this long-term study were that children with exstrophy do not have clinical psychopathology (Montagnino et al, 1998). There was acting-out behavior rather than depression or anxiety, suggesting that improved outcomes may be achieved through a focus on normal adaptation rather than potential psychological stress. In addition, earlier achievement of continence through reconstructive efforts is potentially of psychological benefit. This work was further supported by Catti and colleagues (2006), who found that QoL in adults was better in those who were continent with a good body image. Reiner (1999) studied 42 children with exstrophy and presented preliminary results suggesting that these patients tend to have more severe behavioral and developmental problems than children with other anomalies, significant body distortion, and self-esteem problems. Reiner has recommended early intervention with the exstrophy patient and family and continuation with long-term psychiatric support into adult life. In a study from Europe, Feitz and associates (1994) found a more positive picture when they evaluated 11 women and 11 men with exstrophy, of whom 9 women (82%) and 10 men (91%) did not manifest any clinical levels of psychological stress. The authors concluded that these adults had a positive attitude toward life. With the use of structured instruments and appropriate evaluation and interviews, Reiner and Gearhart (2006) indicated that all 20 patients evaluated met criteria for at least one anxiety disorder. Older patients experienced waning of anxiety associated with peer discovery of incontinence after successful surgical reconstruction, and all noted intensified sexual activity with age. Data from Reiner and colleagues (2008) from a large series of male patients revealed that 14% experienced suicidal ideation. As they became older, 31% experienced this phenomenon; a few attempted adolescent or early adulthood suicide, and 1 succeeded. These findings underline the importance of screening patients for psychopathology as they age.

In an important study by Lee and colleagues (2006), females were found to have more close friendships, fewer disadvantages in relation to healthy peers, and more partnerships than males. There were no gender differences in adjustment within educational and professional careers, which overall were very good. Ebert and colleagues (2005) reviewed by questionnaire a group of 100 exstrophy adolescents. Education and social integration were high. All patients were heterosexual and almost 50% were sexually active, but almost 60% expressed anxiety about sexual activity. The most important finding was that 94% of patients expressed an interest in psychological assistance, underlining the importance of early childhood intervention.
